The Blood and Urine in Eclampsia.—For the purpose of deciding whether eclampsia is a consequence of insufficient renal activity and can therefore be ascribed to a uremic intoxication, an investigation was carried on by W. Zangemeister (Archiv f. Gyn., Vol. 70, No. 3). An explanation of this should be secured from examinations of both blood and urine. Before any opinion can be expressed on abnormal conditions, it is necessary to be acquainted with the normal relations of blood and urine as found in healthy pregnant women. The same author has already shown that the physiological make-up of blood and urine in pregnancy varies considerably from the non-pregnant state. From an examination of a large number of specimens of the blood taken from eclamptic cases, he does not find that there are any points upon which the uremic etiology of the diseases can be based. There is a diminution in the alkalinity of the blood, and at times an increased molecular concentration, together with a larger amount of crystalloidal nitrogenous bodies, but these must be considered as an accompaniment of the diminished diuresis which is usually present during the course of the disease. The factors just enumerated are subject to greater variations in the blood of eclampsia patients than otherwise. The most noteworthy appearance in eclamptic blood is the extreme variation in the quantity of red cells to the quantity of the blood plasma. The blood contains on an average a larger number of red cells, and in fact may be compared to a "paste of corpuscles." The rapid disappearance, and even more so, the rapid formation of this condition, shows that the cause of this phenomenon is not to be found in an overproduction of these elements. The proliferation itself does not represent the cause of the eclampsia, as it is absent in many instances. Nor does it result from the attacks, as it may appear without any seizures having been present. The only way in which the phenomenon can be explained is that during the course of the disease severe circulatory disturbances occur, as a result of which a considerable amount of plasma leaves the blood. Concerning the urine of normal pregnancy, the author has shown that during the last month, there is an increase in the amount passed during twenty-four hours, the ammonia salts are slightly increased, and the chlorides are about the same as in the non-pregnant woman. The phosphates are, as is well known, decreased in amount—this being ascribed to the fetal bone formation. During labor it was found that less water and salts were excreted by the kidneys than during the period immediately preceding. Especially is the excretion of chlorides diminished; that of the phosphates and ammonia salts is less marked. A very complete series of analyses was then made of the urine of numerous cases of eclampsia. These do not admit of being abstracted and the results obtained do not lend themselves to an explanation of the manner in which the irritation of the vasomotor centers is produced. Whether this is due to toxic conditions or to a reflex nervous disturbance is therefore still a matter of doubt as far as the author's findings are concerned. If one has to do with a toxemia, it may be stated with considerable certainty that the poison does not result from insufficiency of the renal function nor does it leave the body through the kidneys, unless in an entirely changed form a considerable time after the disease has subsided. In other words, for the elimination, or more properly the destruction of this hypothetical toxin, the renal function is not called into play. The poison, moreover, does not bring about any increase in the molecular concentration of the blood. The changes found in the

body in an eclampsia case may also be accounted for without the intermedium of a poison. The author brings forward the following facts as against the idea that a toxin is present: The earlier the course of the pregnancy or the later in the puerperium the attack comes on the more severe it is apt to be, and it is more apt to occur with the first labor pains than after these have been present for some time and have produced a toxin or thrown the same into circulation. Although there may be some basis in fact for assuming the toxic theory, the author is inclined to the belief that this is questionable and that later investigations will show that the eclamptic attack is brought about in some other way, possibly as a purely reflex nervous phenomenon.

Paralysis of Abdominal Sympathetic Following Labor.—After abdominal section, this condition is not of rare occurrence, especially in those cases where a large tumor has been removed from the abdominal cavity. After delivery, Edward P. Davis (Am. Jour. of Obstet., Dec., 1903) finds that there are certain cases where the fetus is unusually large, where there is polyhydramnios or in exhausted women, the same condition is observed. Here the author reports a case where there was no hemorrhage, the child small, and the mother was not exhausted. She was highly neurotic. Her excretions required frequent stimulation during pregnancy. During delivery, extensive laceration was threatened, so the patient was immediately anesthetized by ether and easily delivered with forceps. After labor she complained much of general abdominal pain, and upon examination a doughy mass was found in the left upper portion of the abdomen. Cathartics failed to produce good results, but were succeeded by vomiting and gradually increasing distention of the abdomen. Efforts to move the bowels by enemata were unsuccessful. The temperature varied from 99° to 102° F., but symptoms of sepsis were wanting. Rectal examination showed that there was fecal impaction. The patient was stimulated and given large ox-gall enemata. On several nights there were attacks of syncope. Gradually with this treatment the fecal mass was softened and the bowels cleared. Later predigested food was taken and retained, and she finally made a tedious recovery. Examination after convalescence showed the pelvic organs to be normal, the abdominal walls contracted and tenderness absent.

The Value of Vaginal Cæsarean Section.—There are over 60 cases of vaginal Cæsarean section reported so far, says M. Stamm (Am. Jour. of Obstet., Nov., 1903); the majority of them were undertaken for cancer of the uterus, but the number performed for puerperal convulsions is also rapidly increasing, and it seems that this trouble will furnish the chief indication for the operation in the future. Most authorities seem to agree that rapid delivery is the most important measure in reducing the mortality in eclampsia. The operation consists in exposing the uterine portion by a large speculum or forceps and grasping it with two pairs of forceps on either side of the os. A longitudinal incision 5 to 7 c.m. is then made in the anterior wall of the vagina, down to the os uteri. The loose cellular tissue is then opened with scissors, between the bladder and the cervix. The bladder is pushed back, with a small piece of gauze, and as far as the internal os, and, corresponding to the height, a sagittal incision through the anterior wall of the cervix is added. The upper margins of the wound are grasped with forceps in a manner similar to morcellement and myotomy. This exposes a further portion of the womb, the bladder is pushed up more, and another incision is made through the lower segment of the uterus. If this maneuver is repeated a few times an incision of 8 to 12 cm. can readily be made under the guidance of the eye and without opening the peritoneum. This incision is generally large enough to admit the hand and to extract the mature child. Should it not be sufficient, however, a similar procedure can be followed at the posterior portion. In the majority of the cases it is perhaps best to wait for the natural expulsion of the placenta, or, if it does not follow soon, some pressure can be made upon the uterus. This operation is best done in a hospital, though it can be performed at the patient's house if circumstances are such as to make it an operation for an emergency.

Pseudohermaphrodite.—The essential organ of generation and that which must in the final analysis determine the sex, is the presence of the testicle in the man, and the ovary in a woman. The true hermaphrodite, says J. Riddle Goffe (Am. Jour. of Obstet., Dec., 1903), must possess both these organs. No case of unilateral hermaphrodism has ever been reported. The cases of the older writers usually fall under the bilateral. They are all of doubtful authenticity. An individual with functionating glands of both sexes provided with excretory ducts has never been discovered. The author reports the case of a 20-year-old woman. On examining the genitals an enlarged clitoris with prominent glans obtruded itself and became erectile on the slightest touch. It was surrounded with a corona of hair and surmounted on the mons veneris with a luxuriant tuft. The clitoris measured three inches in length and three and one half inches in circumference. The foreskin could be drawn forward on to the glans, but contracted strongly in erection. A narrow strip of mucous membrane ran along the free border of the frenum, as in cases of hypospadias. The clitoris was impervious and the meatus urinarius could not be discovered. Below the introitus was a broad perineum reaching to the anus. The vaginal opening took a Peaslee sound readily to the depth of 4½ inches, and the caliber of the canal seemed to enlarge at its distal end. Under bimanual manipulation with the finger in the rectum, no internal generative organs could be outlined except a cord-like extension from the upper end of the vagina. The clitoris was removed and the small vaginal opening was enlarged; the skin of the clitoris brought down and grafted upon the denuded vaginal surface. Several months later, the vagina easily admitted the ordinary bivalve speculum.

Ovarian Grafting.—The following are the results and conclusions of Robt. T. Morris (Am. Jour. of Obst., Dec., 1903), obtained from experimental work on a series of rabbits: (1) When the ovaries are removed from an animal, and then replaced at some point near the original site, or even at distant points, the tendency is for the ovary to continue its function of developing ova and of furnishing its internal secretion. Such transplanted ova may continue to do normal work for an indefinite period. (2) When ovaries are removed from one animal and transplanted into another of the same kind which had its ovaries removed, the tendency is for the grafted ovary to undergo degeneration. The graft will continue to develop ova and furnish internal secretion, for several months in some instances, but at the end of a year the grafts are often found fatty and useless. It is to be assumed that the serum of one animal is destructive to the introduced tissues of another of the same sort. Several points of practical value have been arrived at from this experimental work, and may be applied to the work of to-day. If, for instance, in a case of pyosalpinx, one is obliged to remove the ovaries and oviducts en masse, as often occurs, one can place part of a fairly good ovary in a warm saline solution until the rest of the work is com-

pleted, and then graft this piece of ovary beneath the peritoneum at some point near its original site, before closing the abdomen. This may prevent premature menopause. This refers chiefly to grafting a piece of the woman's own ovary. With a piece of another woman's ovary, the patient may menstruate for several months and have the benefit of internal secretion. It may be possible for her to become pregnant before the graft is degenerative, but this has as yet occurred only in rabbits and very shortly after the grafts were introduced. In one patient who had congenital degeneration of the adnexa and who had never menstruated, menstruation was established by ovarian grafting and continued for nearly four years. The method employed by the author in grafting consists in putting a piece of one ovary into a pan of saline solution at a temperature of about 100 F. until the operation is completed. The segment of ovary is then inserted through a slit in the peritoneum, somewhere near its original site, in such a way that the raw surface of the ovary is subperitoneal, where it can be nourished by the lymph circulation until new capillaries are formed for its support. These are very rapidly formed. A part of the normal periphery of the ovary is allowed to protrude into the peritoneal cavity, so that the ova may escape and find their way into the oviducts in cases in which such a possibility exists. One or two fine catgut sutures serve to hold the graft in place.

Modern Theories of Eclampsia.—The old theories of a renal origin of eclampsia hardly fit into the present knowledge of this disorder, and many views have been advanced which make an intoxication with fetal elements possible. The earliest attempt to explain eclampsia in this direction, took for granted a direct poisoning of the system with placental tissue which readily finds its way into the material circulation. Experiments do not, however, bear out this theory, for the injection of placenta into pregnant animals of the same or different species is never followed by symptoms in any way suggestive of eclampsia. According to another theory every animal destroys its own placental emboli by means of a specific antibody, which is produced only too readily in excess and then acts as a poison. Subdural injections of this syncytiolysin have indeed set up eclamptic convulsions, but subcutaneous and intravenous administration is harmless. The following theory seems more plausible to E. Wormser (Münch. med. Woch., Jan. 5, 1904): Poisonous proteid bodies are produced while placental tissue is dissolved in the material blood; these syncytiotoxins are neutralized under normal conditions, but lead to eclampsia if insufficient antitoxin is produced. If specific serum is allowed to act upon the placenta and the resulting emulsion injected into animals, it is very often possible to induce the typical symptom and, what is more important, the typical lesions of eclampsia. The author has repeated all the experiments which have led to the above theories, and can only record negative results. Even the precipitin reaction which is supposed to manifest itself by precipitation when specific serum is mixed with placental in a test tube, could not be obtained. The portions of syncytium which had been treated for several hours had not lost their macroscopic or microscopic appearance, so that a specific action is at best doubtful.

Treatment of Puerperal Fever.—Questions concerning some of the more interesting of the disputed points relative to the treatment of puerperal infection were submitted to a number of distinguished gynecologists by the Internat. Med. Mag. (Nov., 1903). All agree concerning the advisability of emptying the uterus in the presence of symptoms of puerperal sepsis and of retained placenta. The focus of infection should, if possible, be determined. If vaginal, disinfection by douches and local applications after removing sutures from closed lacerations, are in place. If uterine, a single, non-irritating douche is given in the absence of débris, in its presence, the sharp curette should be used, scraping only when the finger has felt decidual and placental tissue. The cavity is then irrigated with creolin or lysol and lightly packed with iodoform gauze. The douche, but not the curetting, may be repeated. Infection involving the appendages is treated surgically per vaginam, where possible. Constitutional treatment must assist the local. Hysterectomy is indicated for suppurative metritis or widespread infection of the broad ligaments if the general condition is fair and the diagnosis can be made, but this is not the rule. The operation must be performed early, before streptococci have invaded the blood-stream. Rubber gloves are used by most men in making examinations during labor and vaginal douching after labor has been abandoned by almost all. The opinions concerning formalin used intravenously are no longer enthusiastic; it seems to be not better than ordinary salt solution and may even do harm. For phlegmasia alba dolens, rest, elevation of the limb and some antiphlogistic dressing are in place.

THERAPEUTICS.

Sulphanilate of Soda in the Cure of Basedow's Disease.—Kirnberger, in Gaz. Sicil. di Med. (Nov., 26, 1903) advises the use of sulphanilate of soda in Basedow's disease, to counteract the auto-intoxication by the excessive production of iodine by the thyroid body. The following formula may be used:

R Acidi sulphanilici.....gr. 10 (ʒ viii.)
Sodii carbonatis.....gr. 8.05 (ʒ ijss.)
Aquæ destillatæ.....gr. 200.00 (ʒ 3ss.)

Dose, 3 to 5 teaspoonfuls a day.

While little change on the hypertrophied thyroid has taken place, symptoms are much relieved by this treatment.

Radium in Ocular Therapeutics.—In the Gaz. Sicil. di Med. (Nov. 26, 1903), the following conclusions are made: (1) Radium in external application is a very powerful analgesic, especially for neuralgia, rheumatism, iridocyclitis, and the severe pains of inoperable cancer. (2) Application of radium can produce a rapid absorption in the interior of the eye, such as an old hemorrhage of the vitreous body, absorbed in ten days. (3) Certain interesting results are obtained in blepharitis. The results obtained from action of radio-active salt of radium, internally and externally, permit the hope that it will soon be possible to sooth gastric or intestinal pains of nervous origin from ulceration or from cancer.

Permanganate of Potassium in Morphine Poisoning.—The action of permanganate of potassium, the true chemical antidote of morphine, is explained by W. O. Moor (Therap. Monatshft., Nov., 1903) as follows: If a certain amount of permanganate is added to an aqueous solution of albumin, a dark brown, homogenous fluid will result, which will precipitate as soon as morphine is added. On testing this precipitate for morphine, negative results are obtained, since the entire amount of alkaloid is oxidized. The same thing occurs in the system and it seems that the oxidized albumin can pass its oxygen over to the morphine just like the permanganate itself. In all cases of poisoning about half a gram should be given internally, but since the absorptive powers of the gastric mucosa are much reduced, it is absolutely essential to inject 10 to 15 c.cm. of a one half per cent. solution. If introduced into the subcutaneous cellular tissue in different parts of the body, abscess formation will be avoided.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, FEBRUARY 13, 1904.

THE RABBIT LOPE.

Of the manufacture of diseases, like the making of books, there is no end, and though the brunt of the output has hitherto been borne by the wise men of the East, it now seems that the West has scored sufficient points in the quality of their investigations to make good their shortcomings in regard to the mere quantities of their discoveries. We have had the golf shoulder, the baseball arm and the ping-pong ankle, the automobile scowl, and now, as a climax, we are brought face to face with the "rabbit lope."

In regard to its etiology, it seems that the high price of beef, mutton, and what is known as "hog meat," in the vernacular of the localities in which the disease has appeared—which are situated somewhere between the Mississippi River and the setting sun—have led the frugal and shotgun-loving population to indulge too freely in a diet composed entirely—as far as meat is concerned—of jack-rabbits. These have been selling freely and in large quantities at the moderate sum of ten cents per rabbit, and have been considered somewhat in the light of a celestial manna, until the pronounced and decided symptoms, which are now attributed to their use as a food, appeared and were reported by Clarke in the Birmingham *Ledger*.

The first deviation from the normal, which appears to have been noticed and which is now considered pathognomonic of the Southern epidemics, in Raleigh, N. C., and Danville, Va., is a dilatation of the pupil, a dropping of the accommodation, and a peculiar and marked effacement of all expression from the countenance of the victim. A look of chastened idiocy, that seems midway between what was reported in the early nineties, as the "baby stare," and that mental condition, in which the patient insists on the decoration of the hair with straws and claims to belong to a royal family. This is followed by an erection and cropping out of the ears, and, in the male patient, by a twitching of the mustache hairs, while the female seems to be possessed of an increased mobility of the muscles of the lips, which, in the more advanced stages, leads to a perpetual labial quivering. Finally the characteristic movement, from which the disease takes its name appears, and the patient seems unable to avoid making sudden bounds into the air, which, says the report, is particularly marked when the sufferer is making unusual haste, such as "in endeavoring to catch a car or in dancing."

The symptoms subside rapidly on the substitution of other foods and the chief interest seems, from a scientific point, to lie in the fact of what there is in the rabbit that could have produced the disease. A liberal diet, on his part, of belladonna leaves, would account for the ocular symptoms, but the atropine contained in them would doubtless have killed him before he met his death at the hunter's hands. And even were this not so, it would not account for the assimilation by the patient, of a train of physical attributes, which up to this time have been considered characteristic of the *Lepus cuniculus* family.

As to the rabbit himself, he is doubtless a good deal of an unknown quantity, and the few things that in the past have been considered as fixed facts, have now, under the light of the researches of modern savants, become jangled harsh and out of tune. The hare that has for centuries been taken as the type of timidity has now, according to the "rabbit-editor" of the Washington *Post*, blossomed into a most bloodthirsty monster, that kills and worries dogs, and which has taken, by right of conquest, the place of bloodhounds in Wild West shows and in peripatetic Uncle Tom's Cabin troupes.

We hear, alas, no more of the roly-poly rab-

bits with their cunning little habits, but we are taught that they have more valor, even if less discretion, than Mississippi bears, and that they, in place of Bruin, should take the post of honor in future strenuous and executive hunting expeditions.

So of the former "Brer Rabbit" of our childhood days, little is left to us, even his left hind foot has lost its cunning, and the dark of the moon no longer finds the quiet graveyard an ambuscade for his destruction. Nothing of his former glory is left, save, perhaps, his reputation for speed, in which (the jack-rabbit particularly) he has been long supposed to excel all living things. And even here, as a final blow, comes a story from Arizona that seems to rob poor Bunny of even that last record and leaves him distanced and defeated, unhonored, if not unsung.

It seems that a rancher, a typical man of the class, that loving his neighbor as himself, yet loves his neighbor's wife a little more than either, had ridden some thirty miles or more to an adjoining establishment, and had been welcomed, not wisely, perhaps, but too well, by the lonely chatelaine of the Western wilds. Later on, alarmed by the heavy throwing down on the piazza floor below, of the saddle of the unexpectedly returned wanderer, and remembering that in those regions a man's pistol was apt to be as quick as his temper, and as liable to go off, he folded his tent and quietly stole away. Dropping noiselessly from the window he sped away toward the rising dawn, across the grassy plain. Mile after mile of the prairie he traversed with head thrown back, with chest extended, breathing the deep inspirations of those who are trained to sprint. Some four miles on he overtook a jack-rabbit, who was scorching on ahead to a belated home. Scornfully he kicked him from his path, saying as he left him far behind, "Sonny, when you see a man that *can* run and *wants* to run, give him room, it's all he needs."

If this be true, we cannot say. Western papers are more apt to dress their facts in ulsters than in tights, but if it is, it is only one more proof of the supremacy of man over beast, the victory of a guilt-troubled mind over animated matter. There are few churches on the plains, and Sunday Schools do not abound. Men do not always read while they run, particularly when the contest is with jack-rabbits, and this does not seem to be a case where virtue had its own reward. In fact, the episode might answer in the negative the question of the Poet of the Sierras: "Is civilization a failure, or is the Caucasian played out?"

PULMONARY SYPHILIS.

In the midst of the reawakened interest in tuberculosis there is apparently a likelihood that physicians may forget or at least often lose sight of the fact that sometimes pulmonary syphilis simulates tuberculosis of the lung so closely as to make the differential diagnosis practically impossible except by the therapeutic test.

In a recent number of the *Practitioner* (Nov., 1903, p. 685) Dr. J. J. Perkins, one of the physicians to Brompton Hospital for Consumptives, in London, reviews the subject of pulmonary syphilis and calls attention to the fact that in recent years in English and American medical literature some striking cases of pulmonary syphilis, in which there eventually could be no doubt of the true nature of the disease, have been described.

One of the first and most characteristic of these cases was reported in the Medical News for August 30, last year. In this case the patient, a woman of about forty years, suffered from miscarriage and later developed cough and dyspnea with rapid loss of weight. In a few months she came down from 135 pounds to only 95 pounds in weight. There was considerable expectoration and though the sputum was examined at three different times by specialists no tubercle bacilli were found. In spite of this the disease was considered to be tuberculosis and the patient was advised to remove to the mountainous region of Southern New York. This advice was given by a prominent pulmonary specialist. She followed the advice, and her physician in the mountains, a man of large experience with tuberculous patients, confirmed the diagnosis of tuberculosis. She recovered somewhat, but as there were evidences of a cavity it was considered only a question of time until the fatal termination would come, and she was advised to return home. As she was suffering from a cutaneous eruption she consulted a dermatologist who recognized her skin lesions as of syphilitic origin. She was put on antisyphilitic treatment and not only did her cutaneous condition at once improve, but her pulmonary affection also. The cough gradually disappeared and she became practically cured.

In a more recent case the patient was a man who had suffered from a chancre some eight years before he came under observation. There had been cough with thick expectoration, some

fever and occasional hemorrhages extending over a period of two years, with a loss of thirty pounds in weight. Careful treatment directed to the supposed tuberculosis failed entirely of effect, but a liberal diet of milk with potassium iodide and mercury in suitable doses brought immediate amelioration of the pulmonary symptoms and ultimately entire relief. The signs of consolidation passed away leaving only slightly impaired resonance and an occasional râle.

Instances of this character show the necessity for the exercise of great care in the treatment of patients with a positive syphilitic history in whom there are pulmonary symptoms, especially if no tubercle bacilli can be found. This constitutes the only pathognomonic differential sign between the two conditions. Where a syphilitic patient has not been exposed to the contagion of tuberculosis, it is well to try the effects of antisyphilitic treatment even for pulmonary symptoms, since, if the pathological condition is specific it will not be long before decided improvement will be noticed. To leave the patient without syphilitic treatment is almost surely to commit him to the hopeless ravages of the venereal disease.

There is one consideration that must act as a warning, however, with regard to the employment of antisyphilitic remedies, unless there are good grounds for sufficient suspicion of the specific nature of the disease to justify it. It is well known that patients who are already tuberculous when they contract syphilis usually suffer from their specific disease very severely. To give such patients large doses of the iodides and mercury with the idea of relieving the pulmonary symptoms by these remedies is almost surely to invite a deterioration of the general condition, in which both affections will make sad ravages upon the constitution. Specific treatment must be used, of course, but with great care, and as far as possible without encouraging that tendency to dissolution of connective tissue which allows tuberculous processes in the lungs to spread in spite of nature's effort to wall them off by layers of this form of tissue.

The problem is indeed a serious one, but therefore all the more worthy of the earnest consideration of American medical men. Attention to the possibilities of these cases is needed if sad mistakes are to be avoided. There is more than a suspicion that such mistakes have in the past been responsible for a number of deaths in young subjects that might have been avoided.

VACCINATION ONCE MORE.

THERE are many places throughout this country where smallpox is reported. Until the end of winter the disease always increases. There is constant necessity therefore for physicians to insist on the advisability of vaccination and to make people feel how much of protection it affords, with very little inconvenience, to say nothing of suffering or danger, if done under proper circumstances, with due precautions. Notwithstanding the enormous number of vaccinations that have been done in the last few years there are still many who have not been vaccinated. We may say in passing that notwithstanding the very large number vaccinated recently there have been practically no fatalities and none at all in which some other factor besides the vaccination itself was not at work. Some recently recorded unconscious experiments on human beings, the victims being themselves the responsible experimenters, are reported from Chicago, and may very well be used in convincing those who still are unwilling to be vaccinated of how much this measure gives of assurance and protection against smallpox, and how much the absence of it lays the unvaccinated open to dangers that practically cannot be avoided in our large cities.

The bulletin of the Health Department of Chicago has the following paragraph from the medical inspector, who investigated the four cases of smallpox that were sent to the Chicago Isolation Hospital during the last week of last year:

"A man from Oswego, N. Y., visited friends upon his arrival in Chicago while he was in the early stage of smallpox. At the first house he visited there were two young ladies unvaccinated, though they are employed in a large down-town department store. Both are now in the hospital with smallpox, having contracted the disease from their Oswego friend. There was also an unvaccinated man at another house visited by this man and he, too, is now in the hospital with smallpox. The fourth case, an unvaccinated young man, traveled on the same car with the Oswego man and visited in the same neighborhood."

Needless to say this individual suffering from smallpox came in intimate contact during his travels in Chicago with many other persons besides those sent to the hospital. The only reason why there are not many more cases reported is that, fortunately, most of the other persons with whom he was brought in contact were vaccinated,

for there has been a very proper zeal for vaccination in Chicago in recent years. The inspector does very well, however, to add, and his expression is true for many other cities besides Chicago:

"There are still enough unvaccinated people in the city to fill the hospital with smallpox cases if they happen to come in contact with the contagion as these four victims did."

ECHOES AND NEWS.

NEW YORK.

Dr. M. J. Lewi has been appointed Associate Medical Director of the Security Trust and Life Insurance Company of Philadelphia. In addition to performing the medical functions indicated by his title, Dr. Lewi will assist Mr. Luper in the discharge of his multiplying duties as General Manager of the company. The doctor is well and favorably known to the medical world as Secretary of the New York State Board of Medical Examiners, and his life insurance experience includes a five years' service with the American Union Life Insurance Company as its Medical Director.

The Merging of Two Medical Journals.—Messrs. E. B. Treat & Co., the publishers of the *International Medical Magazine* and of *Archives of Pediatrics,* have concluded to merge the two journals. The publishers regret that they must discontinue the *Magazine,* and extend to Dr. Reed their appreciation of his editorial labors.

Promotion of Dr. Gies.—At the last meeting of the trustees of Columbia University Dr. William J. Gies, adjunct professor of physiological chemistry, was assigned to a seat in the medical faculty.

Dr. P. B. Hawk, who was assistant in the department for two years, and who received the degree of Ph.D. from Columbia last June, has accepted the position of demonstrator of physiological chemistry in the University of Pennsylvania. Dr. E. R. Posner has succeeded him.

The Late Drs. Fridenberg and Ruggles.—At a meeting of the Medical Association of the Greater City of New York, held February 8, 1904, the following reports of committees were received and adopted: The Committee appointed to prepare a minute in regard to the death of Dr. Edward Fridenberg, late fellow and associate and one of the Charter Members of this Association, respectfully reports as follows: Dr. Edward Fridenberg, whose death occurred on December 9, 1903, was born on August 16, 1857. He received his primary education in private schools in New York City and abroad. In 1877 he was graduated from the College of Physicians and Surgeons, as an honor man of the class. After serving as interne in the Mount Sinai Hospital and the Ophthalmic and Aural Institute, he began general practice in New York City. His predilections being for eye and ear work, he went to Europe in 1886 and devoted two years to further special study, after which he established himself as a specialist in these branches. He was closely identified with the early growth of the Harlem Medical Association, and was twice President of that Society. For many years he was Ophthalmologist to the German Dispensary, and since 1886 he was attending Ophthalmologist and Aural Surgeon to the German Hospital. He was also Consulting Surgeon to the Hebrew Orphan Asylum, Surgeon to the Harlem Dispensary, and at one time Surgeon to the Randall's Island and Harlem Hospitals. As an active member of many local and national associations he was widely known. To those who knew Dr. Fridenberg closely he will always be remembered as a man of erudition and culture, warmly interested in all socio-economic questions, and always giving full vent to his sympathy for the oppressed individual, class or nation. He was generous and magnanimous in spirit and action, and many a young colleague will never forget the support and encouragement which he received at his hands at a time when it was most needed. (Signed) George W. Jacoby, M.D., Samuel M. Brickner, M.D., *Committee.*

The totally unexpected death, on December 27 last, of the honored and lamented Treasurer, Dr. Augustus D. Ruggles, was a great shock to all the Fellows of this Association. Dr. Ruggles was a member of a well-known family of repute in the Revolutionary annals of the country, and at a later period closely identified with the interests of the city of New York. He was proud of having been a graduate of the Medical Department of the University of Pennsylvania, the oldest and still one of the foremost of the medical colleges of America, and throughout his career he ever regarded his Alma Mater with feelings of veneration and loving devotion. Receiving his degree during the early part of the Civil War, his patriotic ardor prompted him to seek a position in the military service, and in the years that followed he won distinction as a surgeon, more especially in the campaigns of the Army of the Potomac, where he nobly sacrificed his health in the performance of duty. The greater part of his professional life was passed in this city, and for many years he did laborious and conscientious work as a general practitioner. In the medical history of New York, Dr. Ruggles will be best remembered as an earnest worker in professional societies. His faithfulness, his zeal, his energy, and his indefatigable industry in this particular field have rarely been equaled, and never surpassed. He was one of the early members of the New York State and County Medical Associations, in the latter of which he was honored with the Vice-Presidency, and both these bodies were largely indebted to him for their success. In later years he was one of the organizers and incorporators of the Medical Association of the Greater City of New York, and also its Treasurer from the beginning; and there are few of us who do not realize that it was in a very great measure due to his untiring efforts that this Society has been placed upon a lasting foundation and has started upon a career which promises a brilliant future. He had not a few devoted friends, and his genial disposition and pleasing address made him a favorite in a very wide circle. It is probable that no one has yet lived who had a more extensive personal acquaintance than he among the medical profession of New York City and its vicinity. In taking note of the death of Dr. Ruggles this Association desires to record a sense of the profound sorrow occasioned by his irreparable loss, and to give expression to its sincere appreciation of the faithfulness and earnestness of his self-sacrificing labors in its behalf. (Signed) John H. Hinton, M.D., P. Brynberg Porter, M.D., Reynold Webb Wilcox, M.D., *Committee.*

PHILADELPHIA.

Phipps Institute Lecture.—The next lecture in the international course on Tuberculosis under the auspices of the Henry Phipps Institute, will be given

by Dr. Herman M. Biggs, Chief of the Department of Health in New York, on Monday evening, February 15, the subject being "The Administrative Control of Tuberculosis." The profession in general is cordially invited to attend this lecture.

Dinner to Dr. Chandler.—Many of the prominent physicians of this city, Delaware and Maryland gave a dinner at the Walton, February 4, in honor of Dr. Joseph H. Chandler, of Centreville, Del., president of the Joseph H. Chandler Medical Club of that State. Toasts were responded to by Drs. Hearn, Chandler, Montgomery and others, Dr. H. A. Hare acting as toastmaster.

Medical Standard Too Low.—Dr. Henry Beates, Jr., President of the State Board of Medical Examiners, is quoted as saying that the reason for so many men failing to pass the examination for inspectorships under the Bureau of Health, as well as those before the State Board, is that the standard of admission to the medical colleges is too low. Before the State Board at its last meeting forty-two per cent. of the candidates failed to attain a passing mark. Had Dr. Beates' own vote sufficed for that purpose, eighty per cent. would have been rejected.

Careless Physicians to Be Punished.—The Board of Health is making examples of those physicians who send victims of contagious diseases to the City Hall or to the Municipal Hospital in carriages or even in street cars. A negro physician has been fined $10 and costs for sending a case of smallpox to the department at the City Hall. Three other physicians have been summoned to explain their failure to report cases of contagious disease.

Vaccination at Philadelphia Hospital.—Visitors to the Philadelphia Hospital are now required to show satisfactory vaccination scars or undergo vaccination before they are permitted to enter the wards of that institution. Inmates of the place are also required to be vaccinated before visiting relatives in the city. This rule is in pursuance of the endeavor to prevent smallpox breaking out among the 5,000 inmates of the institution.

Lectures to School Teachers.—Under the joint auspices of the Board of Education and the Department of Health, a course of lectures on "School Hygiene" to the teachers of the public schools will be opened on February 23. Dr. S. Weir Mitchell will open the course with remarks on the nervous diseases of children. The course includes seven lectures, one of which will be held each week. The lecturers to follow Dr. Mitchell are Drs. H. A. Hare, G. E. DeSchweinitz, H. A. Wilson, Jay F. Schamberg, and D. D. Smith. All have volunteered their services. The course is in the nature of a preliminary to the establishment of medical inspection of schools.

Chronic Cyanotic Polycythemia.—A case of this somewhat rare clinical entity was reported at the Section on Medicine of the College of Physicians, February 8, by Dr. W. E. Robertson, the patient being exhibited. The subject is a Hebrew, fifty years of age. He is one of fourteen children, eleven of whom are dead from causes unknown. The patient had never before been ill, not even having the diseases of childhood. He is a moderate drinker and has not followed any laborious occupation. Two years ago he began to suffer from indigestion and constipation, the latter at times amounting to fecal impaction. Pain was then felt in the left hypochondrium. When first seen three months ago the spleen extended three or four fingers' breadth below the costal margin. Since then it has increased markedly in size, now reaching almost to Poupart's ligament. The patient has no fever and no vomiting. The chief complaints are headache and pain on the left side of the body. Cyanosis varies from time to time. It is most marked on the left side of the body. The blood count shows from 9,680,000 to 9,950,000 erythrocytes, 15,000 to 23,000 leucocytes and hemoglobin of 114 to 116 per cent. The size and shape of the red cells seem to be normal. Blood obtained from puncture of the spleen contained no nucleated red cells. The question of splenectomy in this case is being very seriously considered.

To Extend Crusade Against Tuberculosis.—Preliminary announcement of a far-reaching crusade against tuberculosis has been made by Director Martin who is acting in conjunction with Mayor Weaver. Registration of cases of the disease is to be the first step in the plan as outlined. Added to this will be the removal of infected persons to a camp to be established in a mountainous region of the state. The cooperation of the state authorities is to be enlisted as the camp would at first have to be sustained by grants, though it is believed that it could be made self-supporting later on. The scheme as outlined will take considerable time to put into working shape, but it will be pushed as fast as the necessary aid can be secured.

CHICAGO.

Report of the Alexian Brothers' Hospital.—According to the report of this institution, during 1903 the hospital cared for 3,062 patients; 1,932 were discharged cured, 488 discharged improved, and 91 discharged unimproved. The deaths of the year numbered 333. Of these, 126 were in a dying condition when brought to the institution.

No More Expectoration on Sidewalks.—According to the line of campaign recently adopted by the Progressive Health Club, composed entirely of women, there will be no more expectoration on sidewalks, in public places, or vehicles. The members of this club urge the wide publicity of the anti-expectoration ordinance, aided by the press and printed cards, the latter to be brief and forcible. Prompt arrest of flagrant offenders. Alderman Goldzier, who secured the passage of the anti-expectoration ordinance three years ago, which, by the way, has never been enforced, has drafted a formal memorial to Mayor Harrison and the City Council, as follows: "(1) The police and health departments shall be instructed to cause the arrest of persons who flagrantly and offensively violate the ordinance by expectorating on sidewalks, etc. We are fully aware that it is not possible to arrest every offender, but an occasional arrest would call the attention of the public to the ordinance and the nuisance. (2) The present printed card in use by the health department is prolix and weak. (3) These notices to be given proprietors of halls, etc., and posted on patrol boxes and other practical and conspicuous places. An ordinance to provide for their posting in public vehicles." The Committee of the Progressive Health Club was instructed to again call on the transportation companies in the interest of cleaner cars and to secure cooperation from the Board of Education in bringing to the attention of school children the evil of the spitting habit, that they might take the lesson to their homes.

Hospitals Must Comply with Building Ordinance.—The Superintendents of 13 hospitals have been notified by the Building Commissioner not to receive any new patients until certain specified

changes, looking to the safety of patients in case of fire, have been made.

Factors That Influence Pneumonia.—Dr. Wm. K. Jaques read a paper on this subject before the Chicago Medical Society. Among other things, he said that pneumonia is a disease of impaired vitality. Loss of immunity is usually the last factor in causing the disease. When any portion of the lung tissue loses its resistance, one or more of several organisms may cause pneumonia if they are present and are capable of taking advantage of the loss of immunity. The triumphs of medical science in other diseases tend to lengthen life and increase that class of individuals who die of old age. In every community there are people who have passed the meridian of life in seeming fair health, but crippled kidneys, impaired hearts, cirrhotic livers or sclerotic arteries prove they have no resistance when attacked by pneumonia. Because of these complications, there can be no definite and unvarying course in the treatment of the disease. Each case presents its own problems. But there are several cardinal points upon which every physician should have a well matured line of action. These are control of temperature, adequate supply of oxygen, proper administration of nourishment, and attention to elimination. If the microscope reveals the presence of the *Diplococcus lanceolatus* in sufficient numbers to indicate that it is the chief bacterial factor in the inflammation, the prompt administration of pneumococcus antitoxin is a rational procedure. This should be done with the appreciation of the minor part the pneumotoxin may play in the disease. The proper administration of remedies should not be discouraged, but they should be given with a clear understanding that life depends upon the resisting metabolism of the cells, and that medicines are given to increase this. In considering prophylaxis, the most important point to remember is that pneumonia is an infectious disease, and that the infection should be destroyed as near its source (the patient) as possible. The fact that many pneumococcic cases occur where there is a tuberculous lesion makes the discharges from such patients doubly dangerous. Heat is the safest method of disinfection. Boil or burn as many of the infected articles as possible. Furniture, which cannot be treated in this way, should be thoroughly cleansed with soap and water, and then disinfected with formaldehyde. It should be remembered, in the use of this gas, that dried pneumonia sputa, and the horny resisting tubercle bacilli can be but little affected by it in the way it is usually employed for disinfection. Cleanliness is the first and best half of disinfection. Burn, boil and scrub; lastly, disinfect.

Treatment of Burns and Scalds.—Dr. Charles MacLellan read a paper on this subject at the Chicago Medical Society. The clothing should be removed by cutting with sharp scissors, never by pulling or tearing. The washing should be done, if necessary, by effusion of rain or distilled warm water, in which a large quantity of bicarbonate of soda has been dissolved. The blisters should be opened and the evacuated contents absorbed by soft cotton or sponge. As a blistered cuticle never reunites with the cutis, and is not pervious to serum, it should be removed at once and not left to rest on the inflamed cutis after the fluid is discharged, for it must exercise a deleterious influence on the abraded surface, even to endangering the life of the sufferer. The means of supplying fresh cuticle is vested in the cutis, and is begun the moment the injury has been received. The pain in extensive burns is less than is generally supposed, not at all so acute as in injuries of equal extent from other causes and frequently gives little warning to the surgeon in cases where the life is in danger. The surgeon should be careful of albuminuria, pneumonia, meningitis, or intestinal ulcer. The usual local remedies are equal parts of linseed oil and lime water, olive oil, lard oil, dry cotton, glycerin, carbolic acid in solution, starch, gum tragacanth, collodion, etc. These, in the opinion of the essayist, are too adhesive. All detached dead matter should be removed with the dressings once daily, and the old injunction, change the dressing as seldom as possible, may be disregarded. He has in his own practice dismissed all dressings except castor oil in the treatment of scalds and burns of whatever class. In the use of castor oil the author has been pleased with the results, as compared with the former use of the time-honored carron oil, powders or varnishes. It requires a high temperature to keep the parts free from pain, and cotton-wool should thickly cover all dressings in the early treatment. The manner of applying the dressings of castor oil is first to have the parts washed as well as may be. The oil is then poured over the injured surface freely and distributed evenly, with a fine varnish brush, say of an inch and one-half width. Pieces of plain or medicated gauze cut into the desired shape and having previously been placed in a bath of castor oil, are applied over the wound and brushed to smoothness. More oil may then be brushed in to saturate thoroughly, and the gauze then covered with cotton-wool chiefly. The nurse should be instructed to remove the wool at intervals sufficiently close to prevent drying or adhesion, and, having the oil in a vessel at hand, dip the brush into it and paint over the gauze to full saturation, replacing the wool. The removal of the wool and the brushing will require to be done much more frequently in the early days of the treatment, when the heat of the inflamed parts is so great, than when the case has advanced.

Treatment of Trigeminal Neuralgia by Injections of Osmic Acid.—Dr. John B. Murphy reports the case of a man of seventy-six years, in poor physical condition, who had suffered from neuralgic pains on the right side of the face for thirteen years, but they were not very severe or constant until four years ago. On examination slight tenderness was found over the supra- and infraorbital divisions at their exits. No areas of hyperesthesia or anesthesia, and no evidences of tumor or inflammation along the course of either nerve. The proper treatment to employ was puzzling, on account of the patient's age and poor physical condition. It was finally determined to resort to the method used by Bennett, with most gratifying results, in ten cases, namely, intraneural injection of osmic acid solution. The nerve is exposed through a small incision about one-half inch in length, over the supraorbital notch, the incision being parallel with the eyebrow; the incision should be through the mucosa of the mouth or the infraorbital and mental branches. The nerve is elevated by a blunt hook and from five to ten minims of a fresh 1.5 per cent. solution of osmic acid injected directly into its substance and into the foramen. An ordinary hypodermic syringe and fine needle are used, and the solution injected in several different places to be sure every fiber was reached. A small amount was then injected between

the nerve and its sheath, in its bony canal. During the injection a small pledget of cotton is held around the needle, to absorb the excess of solution. Wherever this comes in contact with the blood or soft parts, immediate blackening results. The action of the acid on the nerve endings in the wound is probably beneficial, so a small amount should be allowed to come in contact with them. The incision is closed with horsehair and catgut, and primary union is not interfered with. The author's case was operated on under ether, though local anesthesia is better for the majority. The operation lasted only some twenty minutes, and when last heard from, Dec. 3, 1903, there had been no return of pain. The modus operandi of the procedure is not definitely understood at present, according to Murphy. The acid acts in one of two ways, or possibly in both; first, by producing a degeneration of the nerve on the proximal side toward the ganglion; or, second, by causing local destruction of the nerve and its endings. The former seems to the author to be more likely. He has now used it on seven cases of trifacial neuralgia, and all have been completely relieved. There is a total loss of sensation in the face over the areas supplied by them, and that anesthesia has existed up to the present time. The masseter and temporal muscles, however, were not paralyzed in any of the cases as far as he has been able to determine, indicating that the degeneration had not ascended on the nerve branches. He used it in one case of neuralgia of the arm, following forearm amputation. Patient's pain was symptomatically located in the palm and wrist of the amputated hand. The injection was made in the three divisions of the brachial plexus, solution 2 per cent., into the trunks for a full inch of the nerve. There was a partial paralysis of the muscles of the arm. The sensation was very much altered at once, and while the patient had suffered from the pain for about ten years, and had had a number of operations of nerve resection, all without relief, the osmic acid produced a change in the location and character of the pain, but it is not sufficiently relieved to call it at all satisfactory, and ten weeks now have elapsed since the operation. In the animal experiments, with injection into motor nerves, permanent paralysis followed. It should, therefore, not be used in neuralgias of motor nerves.

CANADA.

Personal.—Dr. J. W. Daniel, a prominent and popular physician of St. John, N. B., has been chosen to contest that constituency in the pending by-election for the Dominion House of Commons. He is standing in the Liberal-Conservative interest.

Dr. A. J. Richer, secretary of the Montreal League for the Prevention and Cure of Tuberculosis, has returned to that city after an extensive trip to the United States, where he has been obtaining information as to the work of such organizations; studying methods in use in fighting tuberculosis; plans for sanatoria and details of the work. He also attended the Tuberculosis Exposition at Baltimore on January 25, and the meeting of the Phthisis-Therapeutists of North America, on January 28. At the next regular meeting of the Montreal League, Dr. Richer will give an account of his observations.

McGill Medical Society Celebrates Anniversary.—The Medical Society of McGill University celebrated its twenty-fifth anniversary on the evening of February third, with the Hon. President, Dr. W. F. Hamilton, presiding. This Society was formed twenty-five years ago with Dr. Wm. Osler as its first president and Dr. F. J. Shepherd, as first vice-president. A feature of the evening's celebration was a debate on "Resolved, That Athletics Interfere with the Best Physical and Mental Development of the Students." The decision was awarded by the judges, Drs. C. F. Martin, R. Tait McKenzie and D. D. McTaggart, in favor of the negative, as in their opinion athletics did not signify sports as they are carried on in most modern universities.

Winnipeg Medical Association.—At the annual meeting of the Winnipeg Medical Association, Dr. McArthur was elected president; Dr. Popham, first vice-president; Dr. Gordon Bell, second vice-president; Dr. Davidson, secretary, and Drs. McKenty, Beatty, Rogers and Crawford, councillors.

Ontario Physicians and the New Assessment Act.—The Ontario Government proposes to make a radical change at the present session of the legislature with regard to assessments, and as the proposed measure discriminates against the physicians of the Province they are up in arms against the measure. At present physicians in the cities, towns and incorporated villages pay taxes on excess of income over $700; and it is proposed to do away with income tax entirely and substitute therefor a "business" tax. Under this new law a physician owning his own property will have to pay his regular assessment tax on property and in addition a "business" tax on half the assessed value of said property. The new business tax will bear especially hard on the young practitioner and the old practitioner in the cities, as in the former instance, as it takes a young man some years to accumulate an income, he is entirely free under the present law from taxation until such times as he is making more than $700 per annum, and in the case of the old practitioner, who has partially retired from active practice, with very little of this world's goods, but will have to pay, not in proportion to his income but on 50 per cent. of the assessed value of the house he owns or rents.

To Train Ontario Teachers in Hygiene.—A medical conference which may have far-reaching results was held in Toronto last week at the instance of the Minister of Education, as the first step in the investigation of school hygiene by the Ontario Board of Health. One result of the conference will likely be the formation of a medical section to take part in the annual meeting of the Ontario Teacher's Convention. Dr. P. H. Bryce, formerly secretary of the Ontario Board of Health, stated that as a result of medical science in Ontario, the deaths in this province were but one-third what they were twenty years ago. Among others who contributed to the meeting were Dr. Charles Sheard, Medical Health Officer of Toronto, and Dr. C. A. Hodgetts, Secretary of the Board of Health, the latter of whom advocated compulsory drill for school boys as the basis for men trained for the militia.

GENERAL.

Ingersoll Lecture.—This lecture will be delivered this year by Dr. William Osler, of the Johns Hopkins Medical School, of Baltimore, Md. The subject will be "Science and Immortality." Further announcements later.

Examinations for Army Medical Service.—The examination of applicants for appointment as Assistant Surgeon in the United States Army will be resumed in Washington immediately after the close of the present session of the Army Medical School; it will embrace the full examination (as heretofore), at the

conclusion of which those found qualified will be commissioned. Full information as to the requisite qualifications for appearance for examination, method of application, nature and scope of examination, etc., may be obtained upon application to the Surgeon General, U. S. Army, Washington, D. C. The examining board will probably reassemble about the middle of April next, and those desiring to present themselves before the board should make application at once. Applicants are restricted in age to thirty years, and one year's hospital experience or its equivalent in private practice is required.

Congress of Polish Physicians.—The Tenth Quadrennial Congress of the Polish Physicians and Scientists will be held this year in Lemberg, Austria, July 20-24. Prof. E. Machek is the chairman of the committee of arrangements, and Prof. W. Sieradzki, secretary. Dr. Francis E. Fronczak, of Buffalo, N. Y., is the representative of the committee for the United States.

Dr. Senn Going to the War.—It is reported that Dr. Nicholas Senn, who was ranking Surgeon-General during the Spanish-American War, wants Chicago to give him $100,000 at once, in order that he may equip a party of twenty-five physicians, nurses and orderlies to go to Japan for service at the front.

Flies and Typhoid.—Prof. Herbert E. Smith, dean of the Yale medical school and also State Chemist, and Edward Mahl, president of the Hartford Board of Health, in the official report of their investigation of the origin of the recent epidemic of typhoid fever at the New Haven county jail, said that flies carried the typhoid bacilli from dwelling houses on one of the streets that skirt the jail premises and where there were several cases of typhoid at the time. They say the germ-bearing flies entered the open jail windows and deposited the bacilli on the food in the kitchen. Seven of the twenty-one jail patients who had typhoid died.

Mortality from Anesthesia in England.—The annual returns of the British registrar general show a steady increase of mortality from anesthesia since 1863. In 1900 there were 140 deaths registered as due to anesthetics. According to Dr. A. D. Waller, (F.R.S.), of the University of London, this is an entirely unnecessary price to pay for the boon of anesthesia, as the chief reason of its payment is ignorance of the most elementary principles of the subject. Dr. Waller believes that deaths from chloroform (the popular anesthetic in England), are due simply to a too great concentration of the inhaled vapor. Using a pump invented by Dr. Dubois, of Lyons, in anesthetizing animals, Dr. Waller has never lost one from chloroform among the thousands operated on. The pump has already been tried to a limited extent on human beings, with entirely satisfactory results. The best percentage of chloroform for anesthesia is between one and two per cent.; there is practically no danger from such a mixture. This can be accurately maintained by means of the Dubois pump. In many ways chloroform is preferable to ether as an anesthetic, and if it could be rendered as safe as the latter, might largely replace it in this country.

Radium Exhibit at St. Louis Exposition.—Dr. George F. Kunz, special agent of the United States Geological Survey, has been appointed commissioner of the radium exhibit at the St. Louis Exposition, and has been authorized to prepare and procure material therefor, comprising radioactive substances of all kinds, and also exhibits to illustrate the action of radium compounds, ultraviolet light, and Roentgen rays upon mineral and chemical substances. This exhibit is to be made by the United States Geological Survey, in the United States Building. There will be a second exhibit of radium and radioactive substances in the Mines Building.

Typhoid Pre-eminence.—The people of Pittsburg, says the New York *Times*, are not at all proud of the fact that for the moment their city takes first rank among American municipalities for its high typhoid death rate and has held it for many years. The Pittsburg *Dispatch* says: "A comparative list of typhoid mortality of all cities in the United States of over 30,000 population for the years 1888-1891, inclusive, shows Pittsburg to be at the head of the list for that period, and Allegheny standing fourth. The only other two cities showing as great a mortality as that of Pittsburg in this table were Lowell and Lawrence, which have since applied the remedy. The census of 1880 showed the typhoid fever rate per 10,000 population to be greater in Pittsburg than in any other city in the United States, Nashville being then a close second. These statistics leave no doubt of the fact that Pittsburg has for a quarter of a century suffered more from typhoid than any other city in the country. We are not aware of any statistics of districts outside of cities. But as to the undesirable pre-eminence of our city in that respect the figures remove all question. The latest data obtainable as to the typhoid situation in Pittsburg and Allegheny showed 3,299 cases and 483 deaths in 1903. This for a population of less than 322,000 should lead to something more than a newspaper discussion of the possible or probable reasons for what would seem to be a continuing epidemic. Why is it that public opinion does not focus in demand sufficiently insistent to command the attention and compel the obedience of the politicians for an expert investigation of the whole subject? The cost to the people of Pittsburg involved in the toleration of such an amount of preventable disease is many times greater than that of providing remedies which would make typhoid exceptional. Doubtless the trouble begins with the city's water supply, but it does not end there. No doubt a large proportion of the cases are due to secondary infection, which indicates a lax administration of the city's health ordinances. That the professional politicians and office holders do not initiate the reforms needed is not surprising; that the people of Pittsburg do not demand them may properly be so considered."

OBITUARY.

Dr. John R. Hinkson died at his home, 544 Greenpoint avenue, Blissville, L. I., Feb. 5. He had been sick only one day. Dr. Hinkson was forty-eight years old. He was a graduate of the Dublin (Ireland) Medical College. At one time he was a professor of surgery in the Bellevue Medical College. Fifteen years ago he settled in the Blissville section of Long Island City, and had since practised there.

Dr. Joseph G. Rooney, of West Hoboken, died Feb. 4, in St. Mary's Hospital, Hoboken. His death was the result of exposure on the night of Jan. 18, when he attended a number of firemen who had been injured at a fire on Jersey City Heights. His hands were badly frostbitten, and subsequently gangrene set in, the progress of which it was found impossible to stop.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, January 23.

THE HEALTH OF LONDON—THE ETIOLOGY OF CANCER—CANCER CURES—PROPOSED STERILIZATION OF DEGENERATES.

MR. SHIRLEY MURPHY, the Medical Officer of Health for the County of London, in his report which has just been issued, states that the death rate in London from all causes per 1,000 living persons was in 1902 only 17.2. The total population estimated to the middle of that year was 4,579,110. This is the lowest rate ever recorded of our metropolis with the exception of that for 1901, which was 17.1. The health of London, judged by its general death rate, has steadily improved since the present system of registration has been in force and the figures for the last ten or fifteen years compare favorably with those for any equal series of years preceding them. Rightly to estimate the value of these figures, however, it has to be remembered that there are several contributory causes of the low death rate. One is that many invalids leave the *fumum strepitumque* of the capital to die in peace in quiet places in the country or by the sea. Another factor to be taken into account is that the population of London is constantly being replenished and its average of health raised by the influx of sturdy immigrants from the rural districts. Statistics have been collected which seem to show that a family of pure-bred Londoners tends to die out in the third generation. Without the constant addition of fresh healthy blood from the country, therefore, our population would be in danger of dying out. It is a sign of ominous import, however, that the birth rate has decreased coincidently with the death rate. The number of births registered in the area over which the London County Council holds administrative sway in 1902 was 132,810, giving a rate of 28.5 per 1,000. This is the lowest birth rate recorded in London since the institution of civil registration. On the other hand there was a slight increase in the number of marriages in 1902, the number recorded being 40,817, giving an annual rate per 1,000 of 17.8, as against one of 17.6 in 1901.

During 1902 cancer claimed no fewer than 4,630 victims in London alone. It is not surprising, therefore, that the causation of that growing scourge is decidedly the pathological question of the day here. The results of a careful study of the subject from the purely biological point of view by Professor Farmer, a leading botanist and two zoologists, Messrs. Moore and Walker of the Royal College of Science, were summarized in a previous letter. These results have since been confirmed in the main by Dr. E. F. Bashford, Director of the Laboratories of the Cancer Research Fund, and his assistant, Dr. J. A. Murray. In a paper presented by them to the Royal Society on January 21, they say that a comparative study of the processes of cell-division indifferent forms of carcinoma and sarcoma occurring in animals yield complete confirmation of the discovery by Farmer, Moore and Walker, of the special and very characteristic forms of cell metamorphosis and division which, previous to their observations on cancer in man, had been accepted as peculiar to the normal reproductive tissues. Drs. Bashford and Murray point out that the transmission of malignant new growths has never been effected from man to animals, or from one animal to another of a different species; but, by the successful experimental transmission of cancer from one animal to another of the same species, it has been found that the tumors which develop are direct genealogical descendants of the cells produced. These conclusions confirm those already obtained by Jensen, of Copenhagen. Artificial transplantation differs from the secondary growths of cancer only in that the latter occur naturally from one site to another in the same individual, while the former is artificially effected from one individual to another. The process is in no sense an infection, for the tissues of the new host are merely the soil in which the transplanted tissue grows, and do not themselves become cancerous. The phenomena of cell division, indicating a similarity to the normal reproductive tissues, may help to explain the nature of this great power of multiplication, but leave the problem of the origin of cancer practically untouched. They give, however, important indications of the character of the processes on the elucidation of which the solution of the question depends. The wide zoological distribution of malignant new growths, which have been found in all classes of vertebrates down to the lowest, indicate that the cause of cancer is to be sought in a disturbance of those phenomena of reproduction and cell life which are common to the forms in which it occurs. If the observations of Farmer, Moore and Walker are finally proved to be correct, it will be established that a cancerous growth in man is precisely similar to the abnormal production of prothallial tissue on the fronds of a fern—in other words, that the onset of the disease in the human being is indirectly due to some of those as yet imperfectly understood causes which like the tying down of the frond of a fern, induce the normal tissue of the body to enter on the reproductive or "reduced" phase of its life cycle. It is pointed out that the new discovery, if established, may open up a large field of possibilities in regard to cure. It is known that the processes involved are in some cases, as in ferns, already under partial, if not complete control; and from this it may be inferred that the cure or arrest of the process in the human subject is equally possible. At the present stage of the inquiry it would be too much to say that the Sphinx-riddle of cancer has found its Œdipus. But it is permissible to say that the work of Farmer, Moore and Walker is considered by some highly competent judges here to be the greatest step yet made toward a solution.

In the meantime the search for a "cure" is being actively pursued in other directions, but it must sadly be confessed that so far the paths followed by different explorers have led nowhere. A couple of months ago we were all somewhat excited by reports of a wonderful discovery made in Germany. It was said that one Schmidt, of Cologne, had not only run to earth but had succeeded in cultivating the elusive parasite of cancer. Sterile cultures of the organism injected into cancerous tumors were said to produce a local selective reaction. After the reaction had passed off, and the process had been repeated several times, it was alleged that the growth, metastatic deposits and infected glands underwent fibrous degeneration. An English practitioner brought the "discovery" to the knowledge of the profession in this country, but the details of the method of preparing the therapeutic serum were kept secret. Schmidt who promised to reveal everything to the Berlin Medical Society has, as far as I am aware, not yet done so. His serum has been tried here under his own supervision on several cases in the Middlesex Hospital without any appreciable result. At a recent meeting of one of the Divisions of the British Medical Association Mr. D'Arcy Power, of St. Bartholomew's Hospital presented a record of three cases—one of cancer of the breast, one of epithelioma of the tongue, one of malignant growth in the neck—treated by Schmidt's

method. In all the cases an operation had been performed not long before. Mr. Power's conclusions are (1) that there is no doubt that a reaction takes place after the injection of Schmidt's serum. The temperature rises and with it the pulse, but the respirations as a rule are not affected. It cannot, however, be said with accuracy that the reaction is specific, as is shown by the fact that in the case which showed the most typical reaction, subsequent examination of the tissues failed to detect any malignant disease. (2) The local effect upon the tumor was shown in each case, for the breast in the first case and the malignant masses in the other two cases became inflamed and reddened as the result of the injection. Here, again, Mr. Power could not satisfy himself that the serum acted by selection upon malignant tissues only. It seemed to him to intensify any pre-existing inflammation. (3) The treatment was certainly painful apart from the succession of hypodermic injections. Lastly, malignant disease progressed while the injections were being given. Mr. Power fears, therefore, that the method at present is of no service either from a prophylactic, diagnostic, or curative standpoint.

The name of Dr. Robert Reid Rentoul, of Liverpool, is well-known to the readers of the medical journals in this country as for many years he was one of the foremost in the small but active body who regard themselves as reformers, but who are regarded by most people as bores. His persistence as an agitator was rewarded a few years ago by his election as one of the Direct Representatives of the English profession on the General Medical Council. His career there was brief and inglorious. One day he suddenly resigned, possibly because he felt himself to be a failure as a medical legislator. Since that episode, he has been comparatively quiet. Quite recently he has come before the world with a booklet bearing the sensational title "Proposed Sterilization of Certain Mental and Physical Degenerates." Deeply impressed by "the appalling state of physical and moral degeneracy now existing in this country" he has set himself to find a remedy. He points out that in the ten years 1893-1902, no fewer than 73,773 lunatics in England and Wales were discharged as "recovered." In the eight years 1895-1903, 8,933 lunatics were discharged as "recovered" from the asylums under the London County Council; of this latter number 2,285 were readmitted, 1,119 of them within one year of their discharge. "Is it right," asks Dr. Rentoul, "is it just to others that so large a proportion of 'recovered' persons should be permitted to return to ordinary life, there to beget a tainted offspring?" "We might," he says, "and with less danger, send out among the public persons cured of smallpox or plague without having first disinfected their clothes, as release 73,773 persons from asylums as 'recovered' to either resume or enter into conjugal relations." The remedy suggested is artificial sterilization. The treatment is to be applied not only to 'recovered' lunatics, but comprehensively to sufferers from leprosy, cancer, epilepsy, idiots, imbeciles, cretins, weak-minded persons under restraint, persons with advanced organic disease of the heart, lungs, kidneys, "or, in fact, any specific disease liable to be passed from parent to offspring." Prostitutes and sexual degenerates guilty of "crimes against good morals" are to be similarly dealt with; "a surgical, not the present legal, punishment is required." Tramps, confirmed criminals, the victims of venereal disease, and even "backward," "dull" and "weak-minded" children are for the public good, to be made incapable of propagating their species. The operation proposed for this purpose is ligature of excision of about two inches of the vasa deferentia in the male, or of the Fallopian tubes in the female. It must be done of course under the sanction of a properly constituted authority. "Parliament should empower each County Council to yearly appoint a board composed of one person qualified in medicine, one in law, one by the Commissioners in Lunacy, one from the County Council, and one by the Commissioners of Prisons." Not more than two surgeons in each county should be licensed by the Home Office as operators, and an annual report of all operations should be presented to Parliament. Dr. Rentoul has, as will be seen, got his plan thoroughly organized—on paper. Though an Irishman, he is absolutely destitute of the sense of humor and makes his proposal with the most solemn gravity. He sees no difficulties in the way of his reform, and disdains to take into account either popular or professional sentiment. In this country, owing partly to its own deficiencies and partly to the anti-scientific bias so prevalent even among educated people, the social status of the medical profession is already somewhat doubtful. What would its position be if, among other unpleasant associations, the term "doctor" should come to connote a gelder and spayer of human beings?

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Regular Monthly Meeting, held November 28, 1903.

The President, Frank Daniels, M.D., in the Chair.

Purinemia.—This was the subject of the paper of the evening, and was read by Dr. Reynold Webb Wilcox.

Uric Acid in Gout.—Dr. Wilcox said that with regard to the sodium biurate always found in the tophi of gouty cases, there has always been some doubt as to whether it was the cause or the result of the gouty condition, that is, as to whether the deposit of the urate indicated an excess of urates in the blood, or was only due to some other condition causing a disturbance of metabolism with local manufacture of uratic material. Great as has been the doubt as to the cause of gout, however, there has been still more with regard to treatment. Accepting the suggestions as to the relationship of uric acid to the disease, it has long been considered that the principal element in the treatment must be the prevention of consumption of materials likely to produce xanthin derivatives. Very serious doubts have been thrown on this doctrine in recent times, however.

Goutiness.—This is a condition that develops in the gouty individual and is the result of the unstable metabolism which exists in the system and which is likely to lead to interference with the function of any large organ. The metabolic disturbances are extremely important. They constitute the reason for Woods Hutchinson's recent definition of gout "a disturbance of health, with excess of uric acid in the urine." There are cases in which with undoubted symptoms of goutiness there is no abnormal amount of uric acid in the urine. On the other hand, the definition is too wide and includes certain cases that are recognized as bearing no relation at all to gout, for instance the uric acid infarcts, which occur in the kidney of the new-born child, are surely not to be considered either as an index or as a result of the gouty diathesis. It was shown nearly twenty years ago that uric acid in itself is not toxic and that it may be injected with impunity into animals without producing serious results. On the other hand the investigations of urinary analysts, have led us to the realization that a uric acid sediment is not pathological. The solution of uric acid depends on the presence of normal sodium phosphate in the urine and the absence of this salt, or its diminution very

readily leads to the deposit of uric acid as a urinary sediment. It is recognized, however, that there is some relation between the manifestations of gout and especially their alleviation and the presence of an excess of uric acid in the urine.

Lead as a Cause of Gout.—It is very well understood now and generally admitted that the ingestion of lead is a prominent cause of gout. A very large number of those who suffer from gout are workers in lead in one way or another and very few of those who suffer from chronic intoxication by lead fail to have symptoms of gout. It would seem on the new theory that the presence of lead interferes with the metabolism by which the formation of an excess of purin bodies is normally avoided and also their oxidation product, uric acid, is also avoided. Alcohol is a prominent cause of gout, but it is not definitely assured whether it is alcohol itself, or rather the esters and ethers which occur so commonly in the rich wines used by the wealthy classes and also in the malt liquors of the poor.

Diet in Gout.—It has been presumed that nitrogenous products are a prominent element in the causation of gout. Nitrogen, however, must be given. It can not be taken up from the atmosphere. It may be obtained then either from vegetable albumen, or from animal albumin. Vegetable albumin, however, is to many patients a little harder to digest than that which occurs in various flesh meats. Meats, therefore, must be used in moderation. The same thing must be true with regard to vegetable albuminous products. In a word the nitrogenous elements of the diet must be limited in quantity rather than quality. Two ounces of whisky may also be allowed, especially in patients who take considerable outdoor exercise. In those of sedentary habits and who are already burning up, less of the heat-producing material that is ingested than is normally proportionate to the amount of calories needed, these substances must be a source of additional labor to the liver or the muscles and may therefore be a new cause of metabolic disturbances.

The Purins.—In discussing Dr. Wilcox's paper Dr. Ogden said that very little is known about the purins. While they are familiar enough in the physiological chemistry of former years under other names, it is only for a year or two that they have been known as purins. Fischer first gave them this name, before this they were known as the xanthin and allied bodies. They are present only in small amounts even when the twenty-four hours' urine is examined. The xanthin bodies are usually present to the extent of from two to three up to seven milligrams; under certain pathological conditions, however, as in leucemia, and certain of the anemias they may be present in amounts as high as seven centigrams. The purin bodies are certainly very small in amount, as compared to the uric acid usually found. It is of course still a problem in physiological chemistry what the relationship of the purins to uric acid really is. Uric acid as a pathological factor has certainly had its day. All medical men are familiar with Haig's theory, but this is entirely upset by recent research.

Urinary Insufficiency.—Dr. Egbert Grandin said that the basis of the pains in the wrists, in the ankles, in the big toes, as they occur in so-called gout, or gouty conditions, is very interesting. It must not be forgotten, however, that analogous symptoms, preceded the puerperal condition as the result of urinary insufficiency. It is possible that the underlying basis of these painful conditions is a toxemia, whether the source of the poisonous products be the liver, the kidney or the intestinal tract. At the present time to substitute the term pure anemia for toxemia seems scarcely justifiable, as the knowledge of the profession is not sufficiently advanced and a new word will only serve to cloak ignorance and give an idea that something is known that in reality is not.

Intestinal Indigestion and Gout.—In answer to some questions referred to him by Dr. Wilcox, Dr. Ogden said that the products of undue intestinal fermentation may possibly be a basis for gout. Fermentations are usually accompanied by the presence of oxalic acid in the urine. Oxaluria is usually found to occur whenever indoxyl, as Dr. Ogden prefers to call it, is found in the urine. The question arises whether the oxalates are connected with gout. Dr. Ogden has never seen a case in which this seemed to be probable. Hence it would seem that intestinal fermentation is not connected with gout. On the other hand, Dr. Ogden has seen good results in gouty cases from the use of sodium phosphates, whose effect is evidently to lessen intestinal fermentation. In one case with marked symptoms, 10-grain doses of sodium phosphate, used four times a day, in a glass of hot water, before meals and at bedtime, gave very great relief. This remedy sometimes increases the tendency to intestinal fermentation, as every physician who has had much experience with it knows. Recently in diet lists, Dr. Ogden has seen cauliflower and asparagus forbidden and he has wondered what the chemical reason for the prohibition was.

Clinical and Chemical Gout.—Dr. James J. Walsh said that for many years it has been the custom for the clinicians to accept from the physiological chemist explanations for gout and treat his patients in accordance with them. Gout is now getting to be better understood from a clinical standpoint, and it seems to be evident that there are many forms and that not a few of the vague, painful conditions known as gout or attributed to the gouty diathesis, are really manifestations of a hyperesthetic nervous condition irritated by absorption from the intestinal canal of toxic products. In a word, the true solution of many of the therapeutic puzzles would seem to be in the hands of the clinician and in a greater individualization of his cases than in any all-embracing theory from the chemist, which has so often proved fallacious. Dr. Haig's theory has been accepted by practically all the profession, and now is universally admitted to be without any proper foundation in physiological chemistry. Uric acid formerly explained rheumatism and gout; it has been given up completely for rheumatism and must go for all other conditions. There is no such thing in the nicely adjusted metabolism of the human body as an excess of uric acid.

Frequency of Gout.—Dr. Walsh said that the subject is of much more importance here in America than is usually considered. If an American physician be asked what is the comparative frequency of gout here in America and in England he will be apt to say that we may see one-third, or perhaps even one-fourth, or one-fifth as many cases as they do in London. The statistics of Johns Hopkins Hospital for ten years show that for every four patients suffering from gout, admitted to St. Bartholomew's Hospital in London, three were admitted to Johns Hopkins during the same period. Gout is then three-fourths as frequent here as in England. American gout is all earned, not inherited. There are two principal methods by which it can be earned. These are lead and malt liquors. Twenty-five per cent. of all the gout in this country occurs in patients who have a history of working in lead. More than one-half of the remaining cases of gout occur in persons with a history of taking malt liquors. Even our lighter beers in America prove a source of gouty manifestations.

Difficulty of Diagnosis.—The disease is by no means so easy to recognize as is usually considered and very many of the cases here in America are missed. At Johns Hopkins Hospital Dr. Osler reports that one case had been admitted three times as rheumatism, when on its fourth application tophi were found in the ears. At the present time to substitute another word for the uric acid diathesis, by suggesting that there is some other poison in the blood and giving it a definite name, is apt to cater to the easy method of diagnosis which has in the past heaped together a lot of things and called them gouty or lithemic, or due to the uric acid diathesis. Even patients from the lower East Side who come to the dispensaries are now beginning to tell us that they have the uric acid diathesis. Dr. Walsh would plead for a more faithful study of individual cases and for less assumption of knowledge and presumption of chemical explanations where none exist and where to use words is only to have cloaks for ignorance to conceal the fact that as yet medical men are only groping in the dark over problems of metabolism, and besides all this, to hamper the development of rational therapy because of hypothetical remedies.

Apparently Latent Gout.—Dr. Frank Daniels said that where there are no true gouty manifestations there often seem to be painful conditions pointing to the existence of a gouty diathesis. In some of these cases later on tophi have been found. In a certain number of cases a chalky deposit occurs beneath the conjunctiva of the lid—more frequently in children than in older patients. Whether this is to be considered as due to gout is a question that has often proved a puzzle to Dr. Daniels. In some of them there is a gouty heredity, in others no such history can be found and the subsequent conditions are not such as can be considered to be associated with gout.

Dietary Considerations.—In closing the discussion Dr. Reynold Webb Wilcox said that with regard to large amounts of water, certain distinctions must be made. If taken with meals a large amount of water always disturbs digestion and thus increases the amount of uric acid present in the system. If taken between meals water serves to flush out the system, and then there is less uric acid as a rule. It must be remembered, however, that uric acid, as such, does not exist in the blood. The urates may be found, but it is hard to understand how the biurates accumulate at certain points and certainly the theory suggested by Haig for their occurrence, must now be rejected.

Nervous Elements in Gout.—There is now no doubt that nerve exhaustion plays a prominent rôle in the disturbance of metabolism, that must be considered as the basis of gouty manifestations. Dr. Wilcox has one patient to whom, when he comes back suffering once more with gout, he considers it necessary to tell that he has not enough brains to run his liver and his business, and he must take his choice as to which he wants to go on properly. It is well known that important cabinet crises in England always give a crop of gout cases among the political big wigs. This same form of nerve strain also may bring on diabetes, or may make a simple glycosuria become a true diabetes. This constitutes another important bit of evidence of the relationship between the disturbance of metabolism which leads to gout and that which leads to diabetes. Both of them are evidently related also to the diathesis which causes the deposit of fat in the tissues and gives rise to obesity, which is a real metabolic disorder.

Indican as an Index.—Before beginning treatment for gout, indican will always be found present in the urine and the progressive amelioration of the case can best be determined by means of the disappearance of indican. Commonly if any excess of phosphates have been present they will also disappear. As a rule, Dr. Wilcox has considered that oxaluria was also the result of suboxidation processes, somewhat as are diabetes or gout. In certain cases the alternation of sugar and an excessive amount of uric acid in the urine is not unusual.

Sodium Phosphate in Gout.—Some physicians seem to consider sodium phosphate as a possible remedy for the intestinal intoxication which causes gout. The difficulty always has been, however, in the use of this remedy that after a time symptoms of intestinal irritation were set up and even uncomfortable fermentative processes occurred. The reason for this has recently come to light as the result of the investigations of the committee for the correction of the Pharmacopœia. Nine-tenths of all the normal sodium phosphate on the market contains something more than traces of arsenic. This is due to its manufacture from sulphuric acid, made from pyrites containing considerable amounts of arsenic ores. It is not surprising that this form of sodium phosphate should set up fermentations. On the other hand, it is possible that when small amounts of the sodium phosphate are used, the small amount of arsenic administered may prove tonic and alterative and help in the good results sometimes obtained.

Gout and Toxemia.—There is no doubt that purinemia is a form of toxemia due to intestinal fermentation. The endeavor must be to make this term more specific, so as to get at the exact cause of the symptoms in order to treat them properly. Elimination must be encouraged, but, if possible, the formation of toxins must be stopped. It is this that Dr. Wilcox has attempted to do.

In answer to a question, Dr. Wilcox said that the formation seen in the lids of young children are often true gouty tophias, in his experience, he has found biurate in them.

Rheumatism and Gout.—Dr. Wilcox considers that acute rheumatism must be an infectious disease; that arthritis deformans is a spinal disease; that muscular rheumatism is closely akin to gout and that pleurodynia and other similar muscular pains are much more gout than rheumatism. He recalled the definition of the old Harvard Professor who said that muscular rheumatism was so called notwithstanding the fact that it was not rheumatism and was not in the muscles. It cannot always be cured by diet, however, and, if possible, remedies must be obtained for it.

Theory and Observation.—Dr. Wilcox considers that English physicians have made a serious mistake by attributing an activity in these chronic, painful conditions to uric acid, which it does not exercise. This substance must now be taken down from its pedestal and be allowed to sink into the obscurity from which it should never have been permitted to emerge. At the present time advances in physiological chemistry and more careful clinical observation seem likely to give more positive information in the next ten years than the medical profession has acquired during the last fifty. It seems probable then that many of the painful conditions will be found to be due not alone to one factor but to several factors. Something may be learned, too, of the reasons for the affinity of rheumatism for young people and of gout for the old. Possible combinations of gout and rheumatism will in themselves prove a serious and puzzling subject for study, but properly directed clinical observation will undoubtedly throw much light on obscure conditions.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, held November 11, 1903.

The President, William H. Park, M.D., in the Chair.

Typhoid Bacillus Infection of Oysters.—Dr. Cyrus W. Field read a paper on this subject. The work was undertaken at the suggestion of Dr. Park to determine whether or not the oyster could be a means of infection, and if so, under what conditions it would act in this manner. After various experiments, it was found that the best method of infecting tanks in which the oysters were placed for observation was to sow the *Bacillus typhosus* on agar slanted in flasks; this incubated for twenty-four hours, at the end of this period the growth was washed off with normal salt solution; this was poured into the tank and more fresh salt solution added to the flasks to wash off the remaining bacteria. The oysters were removed at the end of certain periods and were examined bacteriologically. At each period five oysters were taken from the tanks, washed and scraped to remove as many organisms as possible from the shell. $^1/_{10}$ c.c. of juice was used to infect each plate; at the end of forty-eight hours 20 to 40 colonies were fished from each plate. They were planted in bouillon and at the end of twenty-four hours were examined in hanging drop and a strongly agglutinating typhoid serum was added. The dilution used was 1-800. If the organisms in the tube did not agglutinate they were thrown out and no further tests were made upon them. If they did they were planted in lactose, agar and milk. In the latter part of experiments he relied entirely upon the agglutination test. No organisms were found agglutinated in this series that did not react as *Bacillus typhosus* to the other tests.

No. oysters	No. bacteria tested per c.c. in infected tank	No. hours in infected tank	No. bacteria in infected tank	No. bacteria in oysters per c.c.	Per cent. of Bacillus typhosus in oyster
5	20,000	24	0	1,200	22
5	14,400	48	0	900	18
5	8,000	96	0	750	9
5	6,500	7 days	0	570	7
5	4,200	9 days	0	490	1
5	4,600	14 days	0	300	0

In the next experiment, oysters were taken from infected tank at the end of twenty-four hours and placed in an uninfected tank—fresh salt water, same as that in the Aquarium, used with all fishes.

No. oysters	No. bacteria tested per c.c. in infected tank	No. hours in infected tank	No. bacteria in infected tank	No. bacteria in oysters per c.c.	Per cent. of Bacillus typhosus in oyster
5	19,500	24	0	1,300	19
5		24	0	650	5·5
5		48		300	3
5		96		240	
5		7 days		200	
5		9 days		210	
5		14 days		190	
		21 days		200	
		28 days		190	

Never later than the end of the second day could the organisms be found in fresh water. This was due to the great dilution in the fresh water tank and their disappearance. On taking the sea water used in these experiments and infecting it with *Bacillus typhosus*, it was found that the organisms disappeared entirely from the water from the sixth to the eighth day. Fifty per cent. were destroyed at the end of twenty-four hours. Some oysters were removed from the infected tank and kept on ice; no diminution was found in the number of bacteria present per cubic centimeter up to the eighth day. The question is, Does the oyster ever come in contact with infected material, and if so, does not salt water dilute and destroy the organism? That is, if taken from deep sea beds and brought to fresh water. Oysters are removed from beds and taken to small or large creeks and deposited at low tide in drinking or fattening houses, built in the stream at its edge, and as the tide rises the house is filled with water which covers the oysters. As the water rises, one can hear the hissing sound made by the oyster in sucking it up. The specific gravity of this water is less than they are accustomed to, and by a process of osmosis the oysters are enlarged, making them fat.

The streams may be grossly contaminated by sewage. Should a case of typhoid occur in a town near the creek and these oysters become infected by discharges from the patient, those eating the oysters would have typhoid fever, as was the case in Middletown in 1894. This epidemic was traced to oysters fattened in a river. Patients lived on the stream near the drinking house and discharges were drained into the river. Wherever the oysters were shipped a typhoid epidemic followed. This condition of drinking houses is still the same in many places where oysters are shipped to the market. The only way is to forbid the sale of fattened oysters, or the establishment of oyster beds where the water might be contaminated, or the process of fattening where the water was or could be contaminated.

Dr. Wm. H. Park, in the discussion, said that if by the work of Dr. Field, and further experiments, it could be definitely proven that the bloated or fattened oyster was a source of typhoid infection, the Health Department would take the ground that oysters in New York sold in the shell, should not be oysters bloated or fattened in creeks, which are more or less grossly contaminated with town sewage which flows into the creeks. It is fairly easy for anyone used to it, to detect the bloated oysters from those taken from the deep sea beds. Those who care most for oysters, do not care for the bloated or fresh water variety; they prefer those from the deep sea, which seem to be safe.

Dr. Manges asked Dr. Field if the fattened oysters had any distinguishing marks, and what was the percentage of their sale in New York.

Dr. Field replied that there were no distinguishing marks to be seen, except by opening the oyster. If they were fat and plump and filled the shell, which normal oysters did not, they were almost sure to be fattened. The more reputable dealers would not handle them. Oyster connoisseurs would not touch them. They would detect the lack of the brackish taste of deep sea oysters.

Dr. Manges said that at Mt. Sinai Hospital there were a large number of typhoid cases each year, but for Mosaic reasons oysters were not consumed by many of these patients. Outside of the hospital, in cases of typhoid fever, he always made a point of asking about oysters. Wherever typhoid had been found in cases of oyster-eating they had been eaten outside of New York. He did not know of any cases arising in this city. He did know of cases of oyster infection coming from places in the neighborhood—Long Branch and Atlantic City. Two years ago at the latter place the water where the oysters were fattened was a splendid culture medium from sewerage contaminations. As far as New York oysters went, he thought we were pretty safe. Everything suspicious in oyster culture should be prohibited and if the Board of Health would make known the point

emphasized by Dr. Field, how to tell the fattened oyster, it would afford oyster lovers satisfaction and protection. Many were afraid of the oyster on account of this agitation.

Dr. Park said that Dr. Field had said that on account of newspaper talk, the demand for oysters had fallen off one-third. It was true they did not know of any such cases in New York, but they could, by such safeguards, make the use of oysters perfectly safe. Not interfere with their use, but rather allow people to use them.

Prof. G. N. Calkins gave a demonstration of the results of his studies on the bodies found in the lesions of variola. The bodies seen were the same as those originally described by Guarnieri and Pfeiffer, and more recently by Councilman, who had placed the material for the present study in Prof. Calkins' hands. It had been fixed in Zenker, preserved in alcohol, and stained by the method described by Borrel in the Pasteur Annals, 1901, p. 49. Three possible cycles of development of the organism have been traced, the most important of which, the sexual cycle, we owe to the observations of Prof. Councilman. This is intranuclear. The first cycle is a simple growth with segmentation into gemmules, which then infect fresh tissue cells. In the third, which also appears to be a sexual cycle, pansporoblasts are formed, which break up, leaving a Restkörper. Vesicular bodies, similar in appearance to those described in the epithelial cells in variola, are also seen in carcinomata and sarcomata, and in the tissues infected by diphtheria, but the varioloid bodies can be distinguished by the fact that a complete series can be traced.

Dr. Tyzzer, in the discussion, gave a brief outline of his work. He said he had made a comparative study of the lesions following vaccine inoculations and the specific inclusions which accompany those lesions. In taking up this work before being fully convinced that these inclusions were organisms, he followed out various hypotheses. In superficial examination, these inclusions may resemble various sorts of degenerations. He sought to trace these inclusions back to included leucocytes, red blood corpuscles, or degenerations of the protoplasm of the cell. After studying a great many lesions he had been unable in any case to find any form which links the typical characteristic inclusion with any of these degenerations. In vaccine lesions he had found that they formed the same series as given by Dr. Calkins for the cytoplasmic forms. The organisms at first lie between cells, become larger by growth, take their position near the nucleus, and finally undergo segmentation into new forms. Concerning nuclear forms, he found none, although degenerating and disintegrating nuclei were found. The experiments had been made upon the tissues of rabbits and various other animals on cornea, skin and mucous membrane. It was quite evident that these inclusions bore some resemblance to degenerations, but after a study of lesions in these various animals and in the various tissues of these animals, he still considered that they are organisms. In the course of this work lesions were studied from a series of one hundred rabbits, several guinea-pigs, two sheep, twelve calves and three adult cows.

Dr. W. R. Brinckerhoff spoke briefly of work done by him with Dr. G. B. Magrath, under the direction of Dr. W. T. Councilman, upon the lesions of experimental variola in the monkey. They found many of the forms described by Prof. Calkins in the lesions of smallpox in man, the work being strongly confirmatory of the work of Prof. Calkins. Mention was also made of a degeneration of certain cells of the testicular epithelium in acute diseases which led to forms simulating a certain stage of *Cytorrhyctes*. He then pointed out the grounds on which such a degeneration product could be differentiated from the parasite.

Dr. Anna W. Williams said that before Dr. Councilman's very important paper appeared, their section work was mainly with rabbits' corneas inoculated with vaccine virus. Since his paper, they had begun the study of serial sections from monkeys inoculated with variolous virus from different cases of variola. This work was practically just begun as they had studied sections from only two monkeys, and she therefore felt some hesitation in speaking about it. She wished to mention, however, one or two perplexing points. Their two monkeys showed a great difference in reaction to the inoculation of the virus. In one, the eruption developed late and was of a mild form. In this one, very few definite intranuclear changes were found. In the other monkey, an early and abundant eruption developed, and both the intracellular and intranuclear changes were marked. In sections from this monkey they had found nearly all of the forms described by Dr. Calkins, but they had not yet been able to trace out the definite, consecutive cycle described by him. In the first place, there seemed to be frequently beginning vesiculation with no bodies present either in the vesiculated cells or in those in their immediate neighborhood. Then the intracellular forms showed an extreme irregularity in the time of their appearance, and in the size of the ameboid forms, and in the size and shape of the segmenting forms, more of an irregularity than Dr. Calkins had described in his remarks. Of course, they knew that they might have degenerative changes in such a protozoon, as well as in the host cell, and that such degenerative changes might occur more frequently in one monkey than another, giving at times a very complicated picture. Such a condition might account for some of the peculiar intranuclear changes which they had found. They had been able to trace a series of apparently undoubted degenerations into which some of the forms shown by Dr. Calkins seemed to fit. A substance appeared in the nuclei in advancing lesions which stained a homogeneous, brilliant pink, with hematoxylin and eosin, and a greenish blue with magenta and indigo carmine. This substance first appeared in small, irregular masses, often by the side of the principal chromatin mass of the nucleus. As the lesion advanced, this substance was often seen partially, and then completely surrounding the chromatin mass, leaving that as a small, more or less rounded central body which takes the chromatin stains as a rule brilliantly. Such a picture seemed to resemble one of the first stages of the primary sporoblasts as described by Dr. Calkins. Other nuclei were more or less filled with this homogeneously staining material, most, however, still retaining a chromatin mass. Many of these later nuclei contained in this homogeneously staining material, irregular granules, some highly refractive, and others not, some larger with a vacuole-like center approaching definite ring bodies in appearance, and some of these with a central granule. It was thought by the speaker that these appearances might be due to mixed protozoan infection and degenerative changes, but, so far, they had been unable definitely to say that they were due to more than degenerative changes.

Dr. James Ewing said that he had heard Dr. Calkins' presentation three times and felt that it had become more convincing in each repetition. From the very first he had been greatly impressed by the examination of the specimens, and had felt that we were probably face to face with the solution of the problem of variola. He had never been quite free from doubt, however, regarding the interpretation to be placed on the intranuclear forms, while in regard to the extranuclear vaccine bodies he believed that no one could afford to ignore the

generally accepted opinion of pathologists that these bodies represent degenerative products. The line of proof thus far brought forward to demonstrate the protozoan nature of all these bodies, intra- and extranuclear, seemed to him incomplete. Very little or no attention had apparently been paid to the possibility of reproducing the intranuclear forms by other methods. In his own study of vaccine bodies he had become familiar with and overwhelmed by the host of structures in necrosing variolous lesions which recall the forms of protozoa, and early concluded that it would be impossible to demonstrate the presence of a definite protozoan cycle on the basis of morphology alone. During the past year he had been attempting to ascertain if vaccine bodies varied in the different animals known to be susceptible, and in any others that might be made to react in any way to inoculations of vaccine; in other words, to establish a comparative morphology of vaccine bodies. He had in this way compared vaccine bodies produced in man, monkey, rabbit, frog, and mud-puppy. The same type of extranuclear body, in general, seemed to be produced by vaccine in each of these animals. One could hardly believe that the same protozoon was capable of growth in animals so distantly related as man and batrachian. He thought that the appearance of the vaccine body in so many different animals could with difficulty be reconciled with the protozoon theory, and seemed to indicate rather that this body represents a universal function of the diseased epithelial cell rather than a particular microorganism invading a cell. Early in 1903, Sikowsky, a Russian observer, reported that vaccine bodies in the cornea could be reproduced by inoculation with diphtheria toxin. In repeating this work he had been greatly surprised to find that within twenty-four to forty-eight hours after inoculation of the rabbit's or frog's cornea with diphtheria toxin practically the same changes were produced as by vaccine. The very numerous forms of bodies produced resembled in striking fashion those seen in variola and vaccine. Some of them were totally different in type from anything he had ever before seen as a result of degenerative processes, and it would have been difficult to have imagined them to be of such origin had any other conclusion been possible. In tracing the origin of these bodies he had come to the conclusion that they originated from a peculiar form of coagulation-necrosis with the production of a semifluid elastic material, which, by comminution and vacuolation reproduced many of the protozoon-like forms of vaccine bodies. This necrotic process involved either the nucleus, or the cell body, or both. It produced minute or large rings and globules, intranuclear or extranuclear, single rings or congeries of vacuoles, rosette-like bodies, and very peculiar cyst-like bodies large and small. Many of them he found indistinguishable from similar bodies he had seen in variolous lesions, and strongly resembled the bodies included in the cycle of the variola parasite. In drawing conclusions from these observations he felt one could not safely claim that no protozoon forms are mixed up with the vaccine bodies in variola, but they did seem to show that the morphological evidence so far presented had failed to demonstrate any protozoa in variola, and that morphological studies alone if limited to variola would probably always remain indecisive.

Prof. Calkins, in closing the discussion, said that he felt quite sure that the bodies he had just described were parasites and not degenerations.

Neurofibroma of Hand.—Dr. D. S. D. Jessup presented a neurofibroma removed from the hand of a woman in April, 1903. The patient was thirty-four years old. Two months previously her attention had been called to a swelling in the palm of her hand. This had increased in size and become painful, and she came to the Vanderbilt Clinic for relief. Examination showed an elongated swelling on the palmar surface of the left hand extending from the base of the second metacarpal bone to the middle of the first phalanx of the index finger. It lay over the flexor tendons of the index finger, was soft, apparently fluctuating, and a diagnosis of tuberculous tenosynovitis was made. Under ether anesthesia an incision was made the length of the growth, and it was then easily dissected away from the surrounding tissues. The tendons were not exposed, but at the ends of the tumor a pedicle was found which proved to be a division of the medium nerve. On reaching the tumor the nerve broke up into small filaments which were distributed over its surface. After removal the growth measured 9 cm. in length, was lobulated, and was 2 cm. in diameter at its thickest points. The consistency was soft. Section after hardening with formalin showed firm white fibrous tissue. Transverse sections were stained by the hematoxylin-eosin, Picro-acid-fuchsin and Weigert methods. They showed a growth of fibrillated connective tissue which was very cellular. The whole tumor was made up of this tissue with the exception of a few bundles of nerve fibers lying on the surface, which corresponded to the nerve filaments noted at the time of the operation. The tumor had apparently sprung from the perineurium and there was no proliferation of the nerve fibers. The patient did not show tumors of any other nerves, and the case was also interesting from the standpoint of surgical diagnosis.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, held December 18, 1903.

The President, T. Halsted Myers, M.D., in the Chair.

End Result in Congenital Dislocation of the Left Hip—Lorenz Method.—This was the presentation of Dr. W. R. Townsend. N. V., female, aged nine and a half years, had no treatment until at the age of five years, when the hip was easily reduced by the Pacci method, and placed in plaster-of-Paris. At the end of six weeks, the plaster having become soiled, it was necessary to change it, but the parents refused to have it reapplied, and nothing further was done. The child walked with marked limp, but did not tire, except after excessive exercise. November 3, 1902, 1½-inch shortening; trochanter one inch above Nélaton's line. On December 26, 1902, Dr. Frederic Müller, at the Polyclinic Hospital, before the class reduced the hip by the Lorenz method and applied a short spica bandage. Three months after the operation the plaster was reapplied. Six months after the operation the limb was brought down to about 45 degrees of abduction. On November 2, 1903, the plaster was entirely removed. Since then the child has been allowed to walk. December 11, 1903, the child walks with very little limp, has no pain, does not tire easily. R. A., 25½; L. A., 25; trochanter about a quarter of an inch above Nélaton's line, limb held in abduction. There is one-eighth of an inch shortening of the bones of the leg, and the radiograph shows great difference in the development of the two femora and the head of the bone in the acetabular cavity. Passive motions: Flexion can be carried beyond a right angle, abduction and inward rotation not limited, extension nearly perfect. This case is presented as a success in a patient beyond the age limit that has been suggested by Lorenz, in which success can be reasonably expected by the non-bloody operation.

Double Congenital Dislocation of the Hip.—Dr. H. L. Taylor presented photographs of the hip which pre-

sented some peculiar features. The child, twelve years old, walked cross-legged with the left leg in front of the right, crossing at or above the knees. The dislocation was not posterior on the dorsum, but superior anterior. The head of the bone was easily felt behind the anterior superior spine of the ilium, and the trochanter and neck could be easily palpated. An X-ray had confirmed the diagnosis. In addition, the child had an equinovarus of the right foot and a left pes valgus. These congenital deformities of the feet had never been treated, and the first step was to correct them, which he had done; the flatfoot by manipulation and tenotomy of the peroneals, and the equnovarus, which was very severe, by a modified Phelps' operation. The hip-joints at present are firm in their new sockets, and for that reason, and considering the age of the child, the speaker did not think it advisable to attempt reduction, but preferred to correct the deformity by the Gant's operation.

Study of Relapse After Reduction of Congenital Femoral Dislocation.—This was the subject of Prof. E. H. Bradford, of Boston. The main points of this interesting paper were as follows: The bony acetabulum nearly always is well formed, but shallow. The cotyloid ligament is the main instrument holding head of femur in position; therefore, in reducing dislocation use just as little force as possible, so as not to weaken or destroy this ligament. This is generally torn by the motions of hyperextension, and pressure forward of head while limb is in extreme abduction. Other causes of relapse: Poor support of plaster spica after ecchymosis and swelling have disappeared and muscular atrophy has occurred. Contractures of injured parts form and hold great trochanter in its position close to tuberosity. When the limb is brought down to normal position, trochanter is held by these adhesions and head of bone is therefore forced to move over edge of acetabulum forward and upward. The paper was illustrated by specimens, lantern slides and models.

Dr. Adams, of Boston, in discussing the foregoing paper, said he had seen a large number of cases come back out of place, and he thought ecchymosis and hematosis resulting from much manipulation during operation, might be one of the causes. He thought in a fair percentage of cases, relapse could be attributed to the insufficient holding of the hip by the plaster cast. He thought an apparatus could be put on a month after operation, which could be slipped off and on in two or three minutes, and the patient examined every two weeks.

Dr. V. Gibney was glad to hear Dr. Bradford and Dr. Adams express themselves on the subject so ably. He had had an impression that the very things criticized were the things we were trying to obtain—that is, atrophy of the muscles, and looseness of the plaster so long as the head had been placed in position and there was good abduction. The constant thumping and weight-bearing function of the body tended to thicken the capsule and make it shrink more or less into a firm capsule about the head. Whether the bone slipped out of place in the plaster or not was not clearly proven. He had seen cases after removal of the plaster, where the head of the bone was not in good position. Dr. Bradford's contention was that this muscular tissue which had been torn, cicatrizes and becomes firm, dense tissue, and as the attempt is made to bring the shaft around into position, this does not yield, but the head slips forward and later on there is, as he had seen in a number of cases, an anterior position, when he had felt sure, at the time the plaster was changed, that there was no relapse. He thought Dr. Bradford had made it very clear, that if there was this shortened dense tissue as opposed to the imperfectly contracted capsule, as the limb was brought around on its axis, recurrence resulted. Dr. Bradford's point was not to overstretch the capsule. The next way of preventing recurrence is to take down the plaster earlier than six months, if the bone is in place, and not give the tissues time to become dense and shortened. These are the two points: Not to stretch the capsule too much, and not to leave too long in position.

Dr. Bradford said the idea was to take the head of the femur and bore a hole large enough to get the center of the head in the center of the socket as nearly as possible, and as much of the capsule and cotyloid ligament that holds it should be saved as practicable. If one wanted to have his trousers held up, he did not destroy his suspenders. Too much stretching should not be done. After the head of the bone was in place, it should be looked at to see whether it had slipped. If it had slipped in the first month, it could be put back.

Dr. V. Gibney asked how he brought it down in good position without interfering with this tissue?

Dr. Bradford said his idea was that in a month that tissue would be cicatrized. It was comparatively loose. One could take the X-ray and see where the head was, and move it or do what was required. It was in a pliable condition in a month. In six months it would not be so easy.

Dr. W. K. Townsend said he was much interested in this matter, especially of late, since the cases done by Lorenz had been taken down. The patient presented at the meeting, done by Müller, was one of the best results he had seen of any operated on at that time in New York. Because failure occurred, it did not follow that the Lorenz method was not good. As far as reducing the dislocations was concerned, Lorenz was the best operator in the world, but the end results showed that there was something in the after-treatment or dressings that needed improvement, as hips apparently perfectly reduced, months afterwards slipped out. The studies Dr. Bradford was making would probably prove of great value. He was working to ascertain why so large a percentage of cases relapsed. Dr. Townsend was not sure the reason of failure was damage of the capsule, nor the facts, as stated by Dr. Bradford, in regard to position. The speaker thought there was no question that the less you damaged a part or tissue, the better the result would be. Damage may have been done in the past by demonstration, to show how a hip could be slipped in and out. The use of a machine in reduction might prove a success, especially in the older cases. The percentage of perfect results or cures, he thought, when all the cases were tabulated, would probably be under 25 per cent. He did not consider an anterior reposition a cure, as the femoral head was not in the acetabular cavity, nor was it proper to report a case as cured under a year, as many that had been apparently cured relapsed shortly after removal of the cast. Those in which the head of the bone slipped out of the socket before the removal of the dressing could only be classed as failures and the shrinking of the body away from the plaster spica might permit this to occur in some cases.

Dr. Taylor said he had been exceedingly interested in Dr. Bradford's beautiful demonstrations and also in the experiences he had had, with others, in taking down congenital hips in the last few months and noting results, and in some things he had seen on the other side last summer. In Paris there were two men who had some ideas on the management of congenital hip which were new to the speaker. Kirmisson made a great point of making the reduction over the inferior border of the acetabulum. After overcoming resistance of the abductors he used hyperflexion, bringing the head opposite

the inferior border, and by rotating outward, it slips over the rim. Dr. Calot, of Berck, made a great point of putting the legs up in the inverted position. He said, as does Dr. Bradford, that closer apposition of the head to the acetabulum may be obtained by inverting the legs. The knees have to be flexed and fixed in that position, and that means that the child cannot walk if it is two-sided. He said the child could get along without walking, and that the weight-bearing feature of the treatment was not necessary. The first actual case of reduction seen was in Paris, by Dr. Bradford, who used a procedure similar to Kirmisson's. The case was one of a girl of twelve years, who was very thin and delicate. Everything was done with the greatest possible deliberation. He used no massage of the adductors whatever, he simply stretched them, and they gave way with perfect ease by that method alone. The hip was reduced in fifteen minutes, including pauses, with very little exertion, and no violence at all. It was probably not so difficult as most cases of twelve years, on account of the thinness of the girl. In Paris and Berck they were taking off plaster splints in five to six months. In Berlin they were taking off the plaster in three months. Some of the cases seen by Dr. Taylor, where the splints were removed in three months, seemed to be as perfectly reduced as those seen here at the end of six, eight and twelve months. An important point was that the operations should be done with more deliberation and less violence. He had done several operations this fall without massage, but they were very young cases, and not convincing. The ecchymosis afterward was very much less. He thought there was a future for mechanical reduction; although he had had no experience with it, it appealed to him on rational grounds.

Dr. Murphy said he had seen the work of Professor Lorenz in Vienna this spring. He had seen a great many good results and some poor ones. He saw Lorenz's after-treatment of all his cases. A great many were attended to by his wife, who seemed to be the head of that department, and was very successful.

Dr. Fisk said that between 1896 and 1899 he had had charge of twelve cases. The last time he had looked up the record, about 60 per cent. had relapsed. He did not mean to say that 40 per cent. were cured. Many cases relapsed because reposition had not been done in a perfect manner, and many secondary displacements occurred through careless after-treatment. The cases should be kept in the wards for the first three months and watched very carefully, and the position of the head of the femur noted by X-ray.

Dr. Townsend said that Dr. Lorenz himself returned to this country and removed several plaster casts. He dictated the notes. He examined four cases; there was not a case of the four which he said was a perfect anatomical reposition. They had been in the plaster he originally applied six months, therefore there was no question as to change of dressing, etc., by different physicians.

Dr. Jäger said in 1900-1901 Dr. Schäder was using an orthopedic appliance in preference to plaster-of-Paris after reduction of dislocation, as did Dr. Hoffa. Dr. Jäger thought subtrochanteric osteotomy valuable in cases of anterior or posterior twists of the neck of the femur; thus allowing the feet to be made parallel without danger of redislocation.

Dr. Myers mentioned a case reduced three times with the ordinary manipulations of Lorenz, each time relapsing. About one and a half years ago he reduced the hip by the open method with the assistance of Dr. Harry Sherman. The head was strongly anteverted, and the capsule, tightly constricted about the head, had previously been reduced with it into the acetabulum. The limb was put up in marked inversion, exion and abduction. Three months later, after subtrochanteric osteotomy, the leg was rotated forward 45 degrees, leaving the head in good position. The boy has a perfectly reduced hip, with almost no motion. Lorenz left the plaster on for six months, for the express purpose of allowing contracture of the abductors, stating that when the limb resumed its original position, the head would thus be driven more firmly into the acetabulum. As to manipulation, Dr. Myers did not think he had gained anything by massaging the adductors. After being held in plaster for six months, the muscles became atrophied, and it would be better to shorten the treatment if possible.

Dr. Adams said that Dr. Bradford had shown in one specimen the leg put up in a posterior position. He thought it would not do in a shallow acetabulum. He thought in a large number of cases when the leg was put in that position, and the leg forcibly adducted, the trochanter acted as a fulcrum on the side of the pelvis to pry the head out of the socket.

Dr. Homer Gibney said that since Dr. Lorenz had visited this country, the surgeons at the Forty-second Street Hospital, had been putting up cases of hip disease in which practically all disease had been arrested and the brace removed, in the short, light-weight plaster spica. The men in the plaster room, Out-Patient Department, at the hospital, put on these casts without any assistance whatever, except such as given by the mother or father of the child. He had recently seen one of the staff applying one. The patient, a child, was on the table, securely balanced on the hip rest and cushions under the shoulders. The doctor was putting on the cast with great dexterity, with no assistance whatever. This is being done every day at the hospital by almost every one on the staff from House Surgeon down to Junior's Assistant.

The Bartlett Machine.—Dr. Bradford said, when using the Bartlett machine, in order to protect the skin, they covered the foot with felt and then over the felt they put some leather free of oil which by soaking was made as soft as moose hide. That was shaped around the ankle the night before. A close hitch of rawhide was put around that. In this way a 300 kilo pull could be put on without the slightest injury to the ankle or knee. For the past year he had been trying to get the joints in position without operation of any sort. He was inclined to think if, as in the case of Dr. Myers, in order to secure the head in place it was necessary to turn the toes in and keep them in, a subsequent osteotomy would be necessary. Dr. Bradford said we did not know how many children had a twist of the femur pointing forward nor how much of a twist was compatible with locomotion; until that was known, care must be exercised about osteotomy. Dr. Adams had examined a number of cases, in which the Bartlett machine was used. A man did not want to talk of cures until the patient had been out of plaster and walking about for a year. Dr. Adams' cases ranged in age from thirteen years to four years. Of the older cases one failed absolutely. That was a boy of thirteen years, with strong muscles. He was cut down upon and afterward it was found that the head was misshapen, and the socket small. By no manipulation could it be put in. The head was shaved and an attempt made to put it in the socket, but it slipped. Two cases of twelve years, were thought to be put in; they were still in plaster. Dr. Adams had examined them and thought they had slipped. In a double case, ten years of age, one was put in but slipped; it will be put in again. The other will be put in also. In a girl of nine years,

the bone was put in; X-ray showed that it had slipped, as was thought because the plaster was loose. One of four years of age went in very easily. It has been taken out of plaster. The capsule is now loose; it may slip. Up to date the record of machine cases is pretty good. Thirty per cent. of cases have been failures; the others apparently have not relapsed.

Dr. Taylor showed a number of instruments: plaster cutters: acetabulum scoop, in different sizes, giving a firm grip; another plaster tool; the old Wolf forceps for separating plaster and prying it up after cutting it. The Adams saw, modified by Mr. Jones, having a very beautiful handle modeled after the ordinary carpenters' saw, giving perfect control; tenatons devised and used by Mr. Jones, with straight edges somewhat advanced from the handle. Dr. Becker's hook for hooking up tendons, etc.

Several plaster-of-Paris pelves were shown by Dr. Myers showing the result in cases of congenital dislocation not operated upon.

Dr. Bradford showed a three months' fetus having a very strong cotyloid ligament, also an older fetus having the same ligament well developed. In another fetus showing congenital dislocation, the ligament was not seen. He showed a specimen of double congenital dislocation in a child of two years. The hips on both sides had been reduced, but did not stay. One was cut down upon and that stayed reduced. The child died of whooping-cough before the second hip was cut down upon. It was found that the bloodless operation failed because the acetabular ring was much smaller than the head. Another specimen was shown, of a child not operated on. The capsule was stretched over the acetabulum, covering it like a drum head. A specimen was shown of congenital dislocation which had been cut down on with the old Hoffa method. A good socket, as was thought, was bored out. The child died of diphtheria. On making a section, it was found that so far from making a satisfactory socket, the new socket was half an inch above the natural socket, which was quite deep and very good.

NORTHWEST MEDICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, held January 5, 1901.

The President, Wm. Egbert Robertson, M.D., in the Chair.

Pancreatitis was the title of a paper read by Dr. John B. Deaver, in which he stated that he did not believe that the disease was such an uncommon affection, but that it was comparatively seldom recognized. After going fully into the anatomical structure and position of the organ, he remarked upon the variation in size and structure of the two ducts (the duct of Wirsung and the duct of Santarini) as shown by the work of Opie thereon; he referred to the close association of the pancreas with the biliary passages, and divided pancreatitis into the acute, subacute and chronic forms, the former being subdivided into the hemorrhagic, suppurative and gangrenous. The most important symptoms are epigastric pain, tenderness, tension and tumor, with or without obstructive jaundice, and evidence of mechanical interference with the mobility of the stomach and duodenum, the point of greatest tenderness is usually about one to one and one-half inches above the umbilicus. It is most frequently mistaken for obstruction of the bowel and may be confounded with gastric poisoning, phlegmonous inflammation of the gall-bladder, or the end of the appendix that is directed toward the liver or epigastrium. He stated the causes to be infection of the biliary passages, infection from the intestines and trauma. It is usually accompanied by fatty stools and total extirpation of the pancreas will be followed by glycosuria.

Dr. John H. Musser then considered the subject from the standpoint of the medical diagnosis, and believed that the reason pancreatitis had been so seldom recognized in the past was owing to the tendency to attribute the condition to other causes, as it was not until the work of DaCosta that jaundice was considered a pancreatic symptom, being always referred to the biliary tract. Among the symptoms he enumerated were epigastric pain, diarrhea, nausea and vomiting and, in the late stages, of the condition tumor. He called attention to the fact that prior to the work of Fitz, Mayo Robson and Oser very little attention was paid to the pancreas at autopsy. He divided the condition into (1) acute pancreatitis without hemorrhage; (2) acute pancreatitis with hemorrhage; (3) chronic pancreatitis. In the first variety there is usually the outpouring of a large amount of serum into the lesser peritoneal cavity, causing rapid effusion, accompanied by epigastric pain, nausea, vomiting and epigastric distention and resistance, with or without dull tympany. The effusion interferes with the action of the lungs and causes the symptoms of dislocation of the heart, and may be accompanied in six to eight hours after the onset with moderate jaundice, and is frequently confounded with gall-stones and intestinal indigestion. Hemorrhage may occur from three to four, or even as late as twenty-four to forty-eight hours afterward, and will be accompanied by symptoms of shock. He reported a case of the first variety occurring in a woman aged over sixty years, accompanied by jaundice and interference with respiration. Operation revealed a considerable amount of fluid in the peritoneal cavity. Drainage was established and the patient made a good recovery. The second variety was illustrated by the case of a man who was thrown from a wagon, and later epigastric pain and vomiting ensued, but no shock; examination revealed a large, dull tympanitic tumor, which was the cause of considerable distress. Exploratory operation showed the peritoneal cavity to be filled with fluid and death ensued in twenty-four hours.

Chronic Pancreatitis.—The symptoms of this disease were enumerated as follows: Flatulency, shock, chronic intestinal indigestion, epigastric pain, obstinate constipation, and diarrhea with fatty stools, and intermittent glycosuria. The patient is usually under middle life, and generally moderately emaciated or very fat, and has suffered from time to time with attacks of pain, which have probably been diagnosed as intestinal indigestion or gall-stones; in these persons as a rule there is gastric atony. If the patient takes a large amount of cream or fat it may be recovered from the stools. In the thin patient there is ptosis of the organ and it is usually very hard, but in the fat patient, physical examination usually shows no evidence of disease of the organ. There are usually present symptoms of anemia (either constantly or at times), gastric disturbance and neurasthenia. He referred to a patient who had suffered from two attacks of pernicious anemia within two years. The X-ray revealed such a mass in the pancreas as would indicate a carcinomatous growth. Operation was performed and the patient made a complete recovery, and at this time it was found that the pancreas was large, hard and indurated, being evidently a pancreas surrounded by a lot of blood. The presence of fatty stools and glycosuria should always excite suspicion, and careful observation, both clinical and laboratory, should be made. He

believed the condition to be one purely for surgical relief, and that the plan offering the surest means of relief was drainage through the gall-bladder.

Surgery of the Pancreas.—Dr. Deaver then considered this subject, in which he stated that hemorrhage should be controlled by tying the tissues of the pancreas, and the bleeding stopped by deep sutures. The great danger in wounds of the pancreas is the escape of the secretion into the peritoneal cavity, preventing the formation of adhesions and rendering secondary hemorrhage probable. Great care should be taken to keep the secretion from the injured gland from the abdominal cavity during the operation and drainage should be established.

Acute Pancreatitis.—This case was also reported by Dr. Deaver. The patient, an alcoholic subject, was operated upon immediately upon his admission to the hospital, prior to which time he had been sick two weeks. The tumor was quite evident on physical examination, and the X-ray demonstrated a shadow that did not move with the diaphragm. Operation revealed no effusion into the lesser peritoneal cavity, but extensive fat necrosis of the great omentum; the pancreas was very hard, but did not feel as though it contained fluid; the gall-bladder, which was filled with stones, was opened and evacuated and drainage established, the patient dying in about forty-eight hours. The operation should be done at the earliest possible moment, the cavity being walled off to prevent the infection of surrounding parts by the escaping fluid. In chronic peritonitis, drainage should be established through the gall-bladder and allowed to continue for from four to six weeks. In gall-stone operations it was recommended that every duct be explored, which it is possible to fathom, in order to avoid leaving any stones.

Dr. Mueller referred to the importance of establishing drainage in the chronic cases, and states that he believed the chief cause of the condition was obstruction of the islands of Langerhans. In the autopsy of the case reported by Dr. Deaver (which he had performed), there was an excess of abdominal fat, the pancreas being in a state of fat necrosis and very hard. The pancreas was in an acute suppurative condition, only part of the field of operation being the seat of hemorrhage. The antrum of Vater contained a few red blood cells: there was marked congestion of the lungs and a little peritonitis in the two upper quadrants of the abdomen.

Dr. Samuel Wolfe remarked upon the meagerness of the literature upon this subject and recommended that all cases presenting symptoms of intestinal indigestion be carefully studied, particularly those in which glycosuria and fatty stools were present. He believed that there was a close connection between the lesions of the Island of Langerhans and glycosuria.

Dr. McGlinn believed that the condition was eminently one for surgical treatment, and recommended exploratory operation in suspicious cases, believing that such procedure with drainage of the gall-bladder would cure many that otherwise terminated fatally.

Dr. Howard S. Anders reported a case occurring in an alcoholic, who reported that he had been a hard drinker and had frequently suffered from attacks of indigestion. Examination showed a small, rapid pulse, excessive perspiration, considerable epigastric pain, and decided tenderness a little to the left of the middle line, but no evidence of tumor or obstruction. Death ensued in a few hours and autopsy revealed chronic infiltration of the pancreas. He also referred to a case which had been under his observation, suffering from severe symptoms of indigestion in the epigastrium, without jaundice, but with a tender spot about the size of a silver dollar a little to the left of the median line, which he is inclined to believe is a case of chronic pancreatitis.

Dr. William Egbert Robertson referred to the accessory pancreas which also contains the Islands of Langerhans, and which he believes are sufficient to prevent the occurrence of glycosuria in large amount. He felt that many of the cases of so-called nervous diabetes could be traced to gall-stones. He also directed attention to the syphilitic variety of pancreatitis.

Dr. Deaver, in closing, emphasized the importance of prompt surgical interference in these cases.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, held January 5, 1904.

The President, Pearce Bailey, M.D., in the Chair.

Ptosis Relieved by Operation.—Dr. B. Sachs presented a young man who had been under his observation for a number of years. He had been apparently well until about ten years ago, when he had an apoplectiform seizure, which resulted in double ptosis and palsy of all of the ocular muscles. There was some recovery, but at the present time there was almost complete paralysis of both recti externi, and the up and down motions were still considerably restricted. The rectus externus of the left side had recovered most. The lesion was evidently in the vicinity of the aqueduct of Sylvius, involving not only the third nerve, but the sixth and fourth nerves. For many years this man had had a very persistent tachycardia, and it was assumed that he had had a chronic endocarditis, and that an embolus had passed into the basilar artery. Quite recently another possibility had arisen, *i.e.*, Dr. A. Wiener had found what he considered to be a specific lesion of the fundus. Possibly, therefore, the original condition was a thrombosis resulting in considerable softening. The speaker thought that after a certain length of time, when the ordinary therapeutic procedures had failed to bring about a favorable result, it was proper to resort to surgical means for relieving the ptosis. Dr. Alfred Wiener, supplementing Dr. Sachs's report, said that before the operation, which he had done, the left eyelid hung down to the full extent. The operation done was that known as the Hess operation. An incision was made along the brow, the skin was dissected away and three deep sutures were inserted so as to practically attach the lid to the frontalis muscle. There had been no sacrifice of tissue, and the natural folds of the lid had been preserved. There were a number of pigment spots on the periphery of the retina, a condition often found in young children suffering from hereditary syphilis. It was extremely probable, therefore, that this man was suffering from hereditary syphilis.

Dr. W. M. Leszynsky said that if the man had a ptosis and a paralysis of the third nerve, and the operation were done, and there was diplopia, the resulting condition would be worse than before the operation.

Dr. Sachs said that he had intended to emphasize the point that if there were a diplopia, other ocular muscles should be cut hereafter and a proper equilibrium of the muscles restored. He had had this done in a number of stubborn syphilitic cases, at the suggestion of an aphthalmologist, and the results had been very satisfactory. He would, therefore, recommend the operation not only in ptosis, but in any ocular palsy of long standing.

Postdiphtheritic Hemiplegia, Probably of Neural Origin.—Dr. Joseph Collins presented a boy of nine

years with paralysis and contracture of the left hand and foot. He had first seen the patient at the request of a surgeon, who suspected a tumor of the cortical motor area. The history was: Two and a half years ago the child had a severe attack of diphtheria, for which antitoxin was administered on the fourth day. A week later the child was very weak, and his hands, feet and face were swollen. About three weeks after the onset of the disease he began to walk, and then it was noticed that the left foot dragged. A day or two later the left hand was observed to be weak. A week or so after that the left angle of the mouth was seen to be drawn up. Oftentimes on attempting to swallow fluids, they regurgitated through the nose. The mother did not recall the boy's having had choking spells on swallowing. Between two and three months after the onset of the paralysis the hand and forearm began to flex and the hand to abduct, so that the elbow stood out from the body further than the shoulder. The hand became tightly clutched and gradually drew up until it was held behind the head. This condition lasted about a year. During this time the endeavor was made to overcome this position of the hand by making him carry a weight in it and by using a Whitely exerciser. About eighteen months after the onset of the paralysis the face became straight, but the condition of the foot remained such that when he attempted to put on a shoe he had to wait until the toes became extended, and if the shoe were not slipped on immediately at that moment he would have to wait half an hour before the flexor contraction or spasm would again relax. He never complained of pain. He attended school during this time, and was always bright in his studies. On admission to the Hospital for Ruptured and Crippled on October 23, 1902, he walked with a limp on the left side, the foot being held in position of marked equinus and slight varus; the left hand was held rigid, with the fingers extended, and the posterior muscles of the leg were in rigid contraction. The toes were flexed. The equinus could be overcome by force. There was slight atrophy of the muscles of the leg, but no paralysis. The left hand was in overextension, but there was no barrier to flexion. On October 28, the astragaloscaphoid articulation was exposed, and a wedge of bone and cartilage was taken from the adjacent surfaces. The flexor longus hallucis was exposed and cut, the proximal end was drawn down and passed through the scaphoid and sutured to itself and adjacent periosteum. The anterior tibial was cut and shortened, and a tenotomy of the tendo Achillis was made. The foot was put up in valgus position in plaster-of-Paris. On November 15, 1902, the hand was put up in plaster in a flexed position. On December 13, 1902, when the plaster was removed from the hand, there was marked flexion with slight flexion of the fingers. On January 21, 1903, it was noted that the hand was in extreme flexion. At present, the boy was apparently healthy and well, except for the deformity of his left extremities. His ability to walk, run and jump was limited only by the flexed position of the foot. He stood on either foot equally well. There was no paralysis of the muscles of the hip. The fingers, hand, forearm and arm were in a state of flexion, and the fingers and hand inclined to extreme flexion. This contracture could be overcome by the examiner. The knee-jerks were present on both sides and equal. There was no tenderness on pressure over the nerves, nor were there any sensory disturbances. There was no atrophy. There was partial reaction of degeneration in the muscles and nerves of the extensors of the forearm and foot, and of the peroneal muscles. There was none of the stigmata of hysteria, unless the contracture might be considered such. The case was diagnosticated as one of postdiphtheritic neuritis resulting in contracture and faulty attitude simulating hemiplegia. That there might be a hysterical element in it the speaker did not deny.

Dr. Joseph Fraenkel called attention to the curious and irregular behavior of the symptoms, and the absence of organic phenomena. The change in electrical reaction might be explained by the clonic state of the muscles. He was inclined to believe that this was a functional disorder.

Dr. Leszynsky said he had carefully examined this boy previously. According to the history that he had obtained, this peculiar attitude took place very rapidly. He had been impressed with the fact that, on entering the hospital, there was complete extension of the wrist and hand, and that after the hand had been placed in forcible flexion it had remained in that attitude, whereas formerly it had been in extension. He could find no evidence of involvement of the motor tract. He was inclined to look upon the case as of functional origin. According to the history, the extension took place quite early.

Dr. Sachs said that from a very large experience that he had had with infantile cerebral palsy he would not hesitate at all to say that this was a case of that kind. He pointed out that infantile cerebral palsy did occur after diphtheria. The boy had a hemiplegia which was entirely typical, and there were contractures just as in other cases of hemiplegia. There were athetoid movements of a most pronounced character. If, with the eyes closed, the boy was asked to grasp one's hand firmly with the well hand, the affected hand would at once go into the athetoid position. He could not recall having ever seen this condition in hysteria or neuritis. The leg had recovered very much more than the arm. He would not deny the possibility also of a neuritis, but the infantile palsy was a primary condition. He could not believe that any neuritis would give rise to the condition found in the leg. He would like to know if any one present had ever seen athetoid movements with peripheral neuritis. There was probably a postdiphtheritic encephalitis as the original cause.

Dr. C. L. Dana said he was very glad indeed to hear this positive opinion expressed because he had arrived at the same conclusion from a rather hasty examination of the child. To him a condition very characteristic of unilateral hemiplegia was present in the face.

Dr. Pearce Bailey said that the history of the case did not point very distinctly to a postdiphtheritic paresis, and such a distinctly hemiplegic character would be unusual for a neuritis. The weight of evidence seemed to point to a postdiphtheritic cerebral hemiplegia.

Dr. Collins said he did not know of any hemiplegia of organic origin that entirely spared the upper part of one extremity. There was some involvement of the face and an inability to wink with the left eye, but a large number of people were unable to wink with one or the other eye who had never had hemiplegia. The fact that one hand underwent extension while the other clutched did not seem to him to have any significance, because he had frequently tried this in persons who had no hemiplegia.

Two Cases of Congenital Cyst of the Fourth Ventricle Associated with Brain Tumor.—Dr. J. Ramsay Hunt reported these cases, presenting photographs and specimens. He said that both cases were examples of brain tumor in young subjects, occupying the left optic thalamus and the right crus cerebri, respectively. In addition, the fourth ventricle in both cases contained a large cyst, primarily attached to its floor, penetrating into the substance of the pons coursing through its

structures and terminating in immediate structural relation with the tumor. The clinical course of the disease in both cases was typical of brain tumor, and permitted the correct localization of the growth. Antedating the symptoms of brain tumor no certain history of central symptoms or mental defect was obtainable. In the second case, the patient was said to have been subject to headaches with attacks of vertigo and nausea. The first patient was a boy of seven, who developed general symptoms of brain tumor with right hemiparesis and right hemiataxia. There was paralysis of the right side of the face with paresis of the left external rectus and with nystagmus. Hearing was impaired on the right. The second patient was a boy of seventeen, who, six weeks after a fall on the occiput developed the general and focal symptoms of brain tumor in the right crus cerebri. Weber's syndrome was present. On exposing the fourth ventricle, at the autopsy, a large cyst was found there in both cases, firmly attached to the floor of this ventricle. By serial sections he had demonstrated that in both cases the cyst dipped down in the pons, coursed forward and was in immediate structural relation with the tumor in both cases. There was nothing in the walls of these cysts to suggest a parasitic origin, while there was much to point to a congenital origin. The frequency of glioma in this locality was well known. The coexistence of a tumor formation still further supported the view already expressed. These cases were unique in his pathological experience, and he had been unable to find their counterpart in the literature.

Case of Primary Sclerosis of the Posterior Columns Followed by a Disseminated Softening of the Other White Columns.—Dr. Joseph Collins presented this report. The clinical picture, he said, was so typical that the diagnosis was made during life. The patient was a house-painter, forty-two years of age, whose only previous illness had been severe attacks of colic. There was no history of syphilis, gonorrhea, or the excessive use of alcohol. In 1900 he began to complain of trembling and stiffness of the hands, associated with intense paresthesia. Later on there was pain in the back. During the following year his principal complaints were manual paresthesia and general weakness. There was no desire for sexual intercourse. All this time he was under treatment for chronic lead poisoning. In January, 1902, he rapidly became paraplegic, and since then had been bedridden. He was admitted to the City Hospital in March, 1902, and when first examined by Dr. Collins, on April 11, the man appeared to be suffering from Bright's disease. He could move the lower extremities slowly; there were knee-jerks present on both sides. The Babinski reflex could also be elicited on both sides. Tactile sensibility was impaired over the lower extremities. Thermal sensibility was preserved, but was slow below the knee. Pain sensibility was preserved. Deep sensibility was lost. There was prompt response to the faradic current. The pupils were equal and responsive. Bed sores were developing over the sacrum. The blood examination showed a predominance of small mononuclear cells and there was only 65 per cent. of hemoglobin. On April 27 it was noted that there was complete flaccid paraplegia; the left lower extremity was edematous; there was incontinence of urine and feces. He refused to take food up to the time of his death. The autopsy was made twenty-four hours after death. The brain and spinal cord was prepared in the usual way, and showed two distinct sets of lesions, sclerosis and softening. The areas of softening appeared to be very recent. In general, they involved the columns of Burdock, the posterolateral portions of the crossed pyramidal tract and the cerebellar tract. The oblongata, pons and motor cortex were normal. The sclerosis appeared to be a primary one following pretty closely the system of fibers in Goll's tract. No thrombi or pathological changes of the blood vessels were found, and the blood examinations showed this fluid to be fairly normal. The genesis of the softening was still obscure.

Dr. C. L. Dana said that this description followed closely those of cases of combined degeneration of the spinal cord with terminal softening. He did not quite understand whether the reporter put his case in this group, yet, to his mind, the case corresponded very closely with typical cases of that kind, a considerable number of which it had been his fortune to observe. Sometimes these cases were associated with a pernicious anemia; sometimes there was a severe primary anemia, while at other times there was no anemia at all. It was unfortunate that neurologists had not as yet agreed upon a name for this affection. The most common name was combined degeneration of the spinal cord associated with toxic states. The pathological conditions reported in this paper were very similar to those already reported. It was only in the minority of cases that there were areas of terminal softening. He was not prepared to admit that there were two distinct processes going on in the spinal cord. The disease began slowly, affecting by preference spots in the posterior columns, and subsequently the lateral columns. If the patient's condition were bad at this time, an acute process developed, but probably essentially of the same nature. The etiology of the toxic condition was as yet unfortunately involved in obscurity.

Dr. Collins said that his case was reported as one of primary sclerosis of the columns of Goll, with secondary softening in the other white columns, the paper being entitled, "A Study of Subacute Sclerosis of the Spinal Cord of Toxic Origin." His case differed materially from those reported by Drs. Dana and Putnam in that the sclerosis was sharply and completely limited to the columns of Goll. In the other cases the sclerosis predominated in the posterior columns and in the crossed pyramidal tract, and this accorded in the main with the clinical history. The fact that his patient had suffered severely from lead poisoning and had subsequently developed a cachexia seemed to throw a little light on the etiology.

Lymphocytosis of the Cerebrospinal Fluid.—Dr. Joseph Fraenkel read a paper on this topic. He said that he had endeavored to study this subject in 47 cases, but in 14 of these the tappings had failed to give any cerebrospinal fluid. There were 7 cases of tabes, all of long duration, and all of these cases showed marked increase of lymphocytosis. Six out of the seven cases of multiple sclerosis showed lymphocytosis. The tapping was done upon the patient in the sitting posture, preferably between the third and fourth lumbar vertebræ, or at the level of the iliac crests. From 5 to 8 c.c. of the fluid were collected for each examination, and then centrifuged. The tappings were made under chloride of ethyl spray. In some of the cases headache and nausea followed lumbar puncture, but they were usually overcome by saline injections.

Dr. Sachs said that in the two cases in which lumbar puncture had been tried by him in order to distinguish between pseudotabes and tabes, the examination proved entirely negative and of no diagnostic value. Hitherto the reports on this subject had been discouraging because of their contradictions. Lumbar puncture should never be attempted whenever there was a possibility of the existence of a cerebellar neoplasm, as several instances of sudden death following this procedure in such cases had been reported.

Dr. Dana said he had made lumbar puncture now in 26 cases, 21 of which were successful. About 12 of these cases were cases of paresis in which it was desired to receive some diagnostic aid. In two the fluid was clear; in others there was a lymphocytosis. He had found the procedure helpful in diagnosticating certain acute cases coming into the insane pavilion. The procedure was easy after a little practice, and could be done almost painlessly by using thirty minims of a half-per-cent. solution of cocaine injected ten minutes before the tapping. The procedure had proved helpful in one or two cases of spinal trouble. He believed it was not only of value in diagnosis, but that it would prove useful in time in therapeutics. Lumbar puncture almost always caused headache or vertigo for a day or two, sometimes for a week, and often it was very distressing. He believed this could be avoided by removing only 4 c.c. of the fluid, a quantity sufficient for diagnostic purposes.

Delirium Grave; a Critical Study, with Report of a Case with Autopsy.—Dr. W. B. Pritchard presented this paper. He said that all authors agreed that the disease was very uncommon, and most writers agreed that it was chiefly found among women. The immediate exciting causes were apparently numerous and various. Typhus and typhoid fever, or other prolonged infections, might be followed by delirium grave. The clinical picture was quite distinct and constant. Following a sudden or prolonged strain, the patient developed a maniacal condition with violence and incoherence. Hallucinations and delusions appeared, usually related to the visual sense, and the temperature was usually raised from one to five degrees above the normal. Again and again transient remissions might occur, but they became less and less complete and less frequent. Emaciation was sometimes rapid, followed by exhaustion, coma and death in a short time. At least two fundamentally different diseased conditions had been confused—one obviously organic, inflammatory and due to toxins or trauma; the other giving chiefly negative pathological findings. He would suggest the use of the term delirium grave for this group, and the application of the terms "pseudo-delirium grave" or "acute febrile delirium" to the first group. Many cases of meningitis and of toxic encephalitis had been reported as delirium grave. In ordinary acute mania there was not the same tendency to rapid and fatal collapse, and the hallucinations and delusions were more systematized. The disease was of extremely grave prognosis, nearly all cases terminating fatally. Death usually occurred from exhaustion; those who escaped death passed into a condition of dementia. The case reported occurred in a woman of forty-three years, who had been subject to many and severe nervous strains. On December 12 she suddenly developed the most violent mania. The delirium and mania were only temporarily controlled by drugs, and she died on the sixteenth day. A noticeable peculiarity was an almost continuous expectoration. Incontinence of urine and feces developed a few days before death. The autopsy was made four hours after death by Drs. McPhee and Larkin. Sections were made from all the regions of the brain. No changes in the blood vessels were noted; the chief changes were eccentricity of the nuclei with ragged cell outlines and loss of chromatic bodies. In the cerebellum Perkins' cells were mere shadows. These lesions had been found in a great many other conditions.

Dr. Adolf Myer was of the opinion that acute grave delirium had, among alienists, much the same position that Landry's paralysis had among certain affections of the spinal cord. The delirium under discussion was uniform and unmistakable in that it could not be analyzed, owing to the excited condition of the patient. He had not yet met with a single case in which there had been reason to doubt the diagnosis of delirium grave. In some of these meningitis had only been discovered by microscopical examination; in others, pneumonia or some other condition had spoiled the purity of the clinical picture. He thought the majorty of alienists took a somewhat different position from Dr. Spitzka on this subject, believing it to be a peracute phase, but not a clinical entity.

Dr. Pritchard said that the object of his paper was to endeavor, if possible, to clear up the subject by separating the cases of meningitis, pneumonia and the like from true delirium grave, and emphasizing this differentiation by reporting a striking case coming under his own observation. He was of the opinion that the vast majority of alienists of to-day did recognize delirium grave as a clinical entity, although of obscure etiology.

SOCIETY OF THE ALUMNI OF CITY HOSPITAL.

One Hundred and Eleventh Regular Meeting, held January 13, 1904.

The President, Alexander Lyle, M.D., in the Chair.

Atrophy Testicle.—Dr. Walter S. Reynolds showed the case of a young man, aged twenty-five years, who presented the unusual complications of an atrophy of the testicle due to trauma received in boyhood on the one side and chronic epididymitis and orchitis on the other. The individual had led a life of a most promiscuous character, having had no less than five distinct attacks of gonorrhea in the past four years. These had all been treated by the usual methods of injection and internal medication. Nevertheless in the last two attacks a very violent epididymitis and prostatitis had developed. The special point of interest in this case lay in the question of the ability of the individual to procreate. It did not seem possible that he could have retained this power in view of the very extensive productive inflammations in and about the epididymis on the right side, while the left testicle had evidently been entirely destroyed by trauma years before.

Dr. Ralph Waldo said that the prevalence of cases similar to the one presented is the indirect cause of many married women visiting the gynecologist. He believes that fully 10 per cent. of all cases of sterility are due to the man. Some years ago he had a patient who contracted tuberculosis of one testicle. After its removal, his wife had a baby. Shortly after this, the other testicle was removed. Five or six years later, although there were no more children, their sexual relations were unchanged.

Dr. J. W. Draper Maury said that a series of experiments had recently been performed on dogs in which the severed vas deferens had been inserted into the body of the testicle, positive proof being afforded later that the spermatozoa were gaining access to the urethra in a normal way. The authors of these experiments, emboldened by their success on dogs, had successfully operated in the case of one man for the cure of sterility which had been proven present, not alone by absence of children, but by microscopical demonstration as well.

Supposed Ureteral Stone.—Dr. Ralph Waldo reported the history of this case. The classic symptoms of calculus were present, but when the abdomen was opened, the following conditions presented themselves: The kidney was bound down at its lower pole to the retroperitoneum. The upper pole had been forced in a rotary manner upward, so that the whole organ had

undergone axial transposition. The defect was remedied by traction and fixation of the organs in normal position. The symptoms, which had been very severe, vanished, and the man made an uninterrupted recovery.

Obscure Rectal Ulcer.—Dr. Carter S. Cole gave the history of an obscure rectal ulcer, the management of which had proven difficult and unsatisfactory. The patient was a woman who had been operated upon in Europe for hemorrhoids. There is no precise information as to what was done, but at the present time, 1½ inches from the surface there is a fine but strong annular contraction. About half an inch from the surface on the wall of the rectum is a small ulcer. This ulcer was not recognized by an eminent stomach specialist and a gynecologist, each of whom had had the patient under observation for many months. Not through any fault of theirs, but because of the diversity of the symptoms produced by the legion, did they fail. The ulcer is positively non-syphilitic. It has been cut out and the site covered with mucous membrane, but it has so far resisted all efforts to heal. It is non-malignant. Nutritive treatment applied directly to the ulcer has been partially successful. He asked for information.

Cerebral Hemorrhage.—Dr. William L. Stowell recited the history of an old woman who presented atypical symptoms of cerebral hemorrhage. She lay in a partial stupor, and at first presented sufficiently marked signs to warrant his diagnosing hemorrhage and giving an unfavorable prognosis. To his surprise, however, in the course of two days she had recovered from many of the symptoms so that his diagnosis seemed to be at fault. One interesting symptom was her inability or her unwillingness to swallow. It is difficult to ascribe this to hysteria in a sensible woman of eighty-eight years. Two days after this effort at recovery, she died.

Dr. Carter S. Cole believed that he had not infrequently seen similar cases and had always ascribed them to basilar endarteritis.

Dr. J. F. Terriberry took exception to Dr. Cole's statement that the condition was one of basilar endarteritis. He said that the more protean and exotic the symptoms, the higher in the cerebral arteries were the atheromatous changes. The difficulty in swallowing was probably mental. Miliary aneurisms are not infrequent in the striate artery. Any profound nuclear lesions give more permanent symptoms than those described by Dr. Stowell. In general, restoration of function means a lesion in the high and unsupported vessels of the brain. Charcot has described the condition. Some of the symptoms presented by these cases are purely mechanical, some are psychical.

Infantile Bronchitis.—Dr. E. Mather Sill presented this paper. He said that out of 1,000 cases of various diseases coming directly under his care at the dispensary in the last two months, 293, or nearly one-third, suffered from different forms of bronchitis. The greater part of this interesting paper was devoted to the methods of treatment employed by the author. He looks very favorably upon the inhalation of oxygen in cases of profound depression arising from involvement of the finer bronchial tubes. Dry cupping over the chest will often relieve the intense congestion of the subjacent parts and will limit the amount of secretion. Spirits of camphor in five-drop doses he has found to be a most excellent remedy. If the child is *in extremis*, the lungs having practically filled with their own secretions, occasionally an inversion of the little patient with the slapping over the buttock and back of the chest will give relief. The general practitioner cannot be too fully warned as to the great danger of routine treatment of these bronchitis cases, each one of which is deserving of very special study and individual treatment. In general, cough medicines designed to allay coughing are contraindicative in children unless their action be very carefully watched. Similarly, all expectorants, particularly the ammonium salts are to be avoided, many a child having been killed by their use. The treatment necessitates first an accurate diagnosis, which cannot be made without frequent examinations of the chest, and second, a recognition of the stage of the disease which is under the physician's care.

Dr. William L. Stowell, in opening the discussion, said that the subject was so old that but little could be added to it. Nevertheless it seemed to him that one point, at least, was of very great importance in determining the treatment of these cases, viz., the condition of nutrition of the patient. The well-fed child needs care and no medicine, the underfed needs support and stimulation of the most accurate kind. This eliminates the abortive treatment by aconite in the foundling. It is useful to remember that all cases bear oily preparations well, a mixture of castor oil, acacia and paregoric forming one of the best relaxing mixtures. The kettle is an invaluable aid in the case of robust children, unmedicated steam being equally good as medicated; fifteen minutes to the hour being none too much in most cases. Every child in the dry stage of bronchitis needs an abundance of moisture to promote ciliary action. This the steam helps, but it is equally important that there should be a copious supply of water from within. To this end the child must drink abundantly. He condemned the cotton batting jacket as useless and dirty, sheet lamb's wool being preferable. In children of resisting skins, where camphorated oil will not produce a good reaction, the oil of camphor can sometimes be used to advantage.

Dr. A. Rupp said that Dr. Sill had not given the attention to calomel in these cases which he thought it deserved. Small doses not only offset the constipation produced by cough mixture, but relieve the laryngeal irritation.

Dr. J. F. Connors urged very strongly the use of ipecac, calomel and castor oil, with a "one to four" mustard plaster, t.i.d. He would cut down the food to one-half or one-third. He rarely uses stimulants and prefers strophanthus when they are necessary.

Dr. A. A. Moore said that prevention should play an important part in the discussion of any paper on bronchitis. He advised that the child should be taken out of doors every day. Along the same lines, the late care of the child, particularly in poorly fed infants, is of ultra importance, and paramount among all drugs or foodstuffs as a preventive of pneumonia, is cod-liver oil.

Dr. Sill, in closing the discussion, denounced the use of proprietary preparations, admitted the importance of calomel and stated that he advised the use of "one to six" mustard plaster rather than "one to four" in tenement house children, because in these neglected cases much harm might be done by the stronger preparation.

Smokers' Ulcer of the Hard Palate.—Dr. Adolph Rupp presented this paper. He said that pathological conditions of the palate, both soft and hard, were not only not numerous, but extremely rare. The lesions which he was reporting had been entirely omitted from the literature on the subject. He presented the histories of the two following cases: *Case I.*—A clergyman, fifty years old, healthy and well-developed in all respects, but an inveterate pipe smoker, developed an ulcer on the roof of the mouth which his physician told him was an epithelioma. It was treated with the X-ray with indifferent success. The lesion was about a half an inch long and a little less in width opposite the second molar tooth on the right side. The border

was vascular and bled freely when touched. The floor was hard. When punctured it bled. There was occasional slight bleeding from this ulcer following swallowing. There was no pain. The patient stated that he had noticed similar ulcers during the past five or six years after excessive pipe smoking. These had previously healed without trouble. This one, however, refused to respond to treatment despite his having ceased smoking altogether. Dr. Delevan saw the ulcer and agreed with Dr. Rupp that it was non-malignant. *Case II.*—A healthy bricklayer, fifty-three years old, smoked a short clay pipe all day. The ulcer was on the roof of the hard palate above the right canine tooth. It was half the size of that in Case I, was quite circular, but the surrounding parts were less congested. The position of the ulcer seemed to have been determined by the difference in the length of the individual pipe stems and the weight of the pipe. The author believed it to be a simple chronic tobacco burn in each case. The treatment was hygienic and local. The teeth were put in order and menthol in absolute alcohol was applied every two hours. A cure resulted very promptly in each case.

Dr. Carter S. Cole, in opening the discussion of this paper, said that it was admittedly a unique condition. In the South many men smoke every day of their lives most of the day. In many of these persons, the end of the stem must come in contact with the roof of the mouth. He had heard of many temporary ulcerations in smokers' mouths, but these had always been near the roots of the teeth. One explanation of the rarity of these cases in medical literature may be due to the fact that they are probably recognized by the individual as caused by the pipe and such prompt healing resulting from abstinence, a physician is usually not called upon to treat the case. Certainly these lesions could not have been malignant or they would not have healed.

Dr. G. B. McAuliffe said that ulcers at the juncture of the soft and hard palate were not uncommon. They are obstinate to treat, many of them yielding only to nitric acid. Underlying these ulcerations there must be something besides tobacco. They are usually regarded as late specific manifestations.

Dr. H. Jarecky had never seen ulcers on the hard palate. Syphilis of the region is easily diagnosed. Tobacco smoke is usually considered to be germicidal. It is not easy, therefore, to understand how it should cause ulceration, unless it be by affecting nutritional disturbance.

Dr. Rupp, in closing, said the different brands of tobacco affect the mouth differently. This is particularly true of cigars. Havana cigars are said to produce carcinoma more frequently than others. Each man had used the same brand of tobacco. Syphilis and malignancy were both out of the question in each of his cases.

BOOK REVIEWS.

Western Surgical and Gynecological Association. Transactions of the Twelfth Annual Meeting, held at St. Joseph, Missouri, December 19 and 20, 1902. American Medical Association Press, Chicago.

The present volume of transactions of the Western Surgical and Gynecological Association is another evidence of what thoroughly good medical work is being done in every part of this country. Many of the papers in the present volume are thoroughly representative of up-to-date surgery. The article of Dr. C. H. Mayo, of Rochester, Minn., on Evolution in the Treatment of Cancer of the Rectum; that of Dr. H. C. Crowell, of Kansas City, Mo., on Carcinoma Uteri; of Dr. Byron B. Davis, on Chronic Pancreatitis and Pancreatic Cyst, and that of Alexander Hugh Ferguson, on A Case of End-to-End Anastomosis of the Popliteal Artery for Gunshot Injury, seem especially worthy of mention. The discussions of these important subjects are typical of the progressive, yet conservative, methods of our best Western surgeons.

Latin Grammar of Pharmacy and Medicine. By D. H. Robinson, Ph.D. Fourth edition. Revised by Hannah Oliver, A.M. P. Blakiston's Son & Co., Philadelphia.

For those students of pharmacy and medicine who, because of various reasons, have been deprived of an academic course in Latin, this work of Dr. Robinson's will prove particularly helpful. It is short, practical, well sifted and well worked out and there is enough good Latin in it to serve as a foundation never to be forgotten.

A Narrative of Medicine in America. By James Gregory Mumford, M.D., Assistant Visiting Surgeon to the Massachusetts General Hospital and Instructor in Surgery in the Harvard Medical School. J. B. Lippincott Company, Philadelphia and London.

This charming narrative is difficult to review, for one is so fascinated by the glimpses of the past, and so carried away by the personalities of the men who have made medicine a science in America that one forgets to pause and note, to jot and criticize, and when one starts to quote a passage that is particularly apt, one cannot refrain from taking whole pages.

The object of the author seems not to have been to rescue from oblivion by exhaustive mention, every medical man of note in America, but rather by describing dramatically the times and the scenes in which characteristic men moved, to give a series of mental pictures illustrating the growth of medicine in Colonial days, Revolutionary times, and through the nineteenth century. He stops, however, respectfully on the edge of the present, not caring to assume, we imagine, the delicate responsibility of grouping celebrities that are still living.

It was a genial conception, not to write only of the medical doings of each physician, but to show that part of his life in which he was soldier, philosopher or friend. In these days when every pamphlet of ours must be adorned on the front page with a triangular slab of fine printing, telling every medical society, hospital, clinic and laboratory that we belong to, we grow accustomed to diverting our personnel from our profession, and when we read a friend's obituary we can no more recognize him in it, than we would recognize the neighborliness of one of our own garden flowers, severed from its root, stripped of its foliage and flattened to show every separate petal in an Herbarium.

This book of Dr. Mumford's is no Hortus Siccus of the flower of the profession. It is somewhat a philosophical bit of history illustrated by men and events. It shows very clearly and chronologically just when and where and why the Art of Healing dallied by the way, was assailed by rogues, and rescued by heroes, and finally led triumphantly forward and honorably presented as the Science of Medicine.

It bears the same relation to other histories of medicine that John Fish's Beginnings of New England does to the text or reference book. It is full of facts, but perspectively grouped and invitingly presented. In short, it is the kind of book that a physician would rest himself with when he was tired, but would turn to for a reference or illustration when he felt fresh enough to wax eloquent over his profession.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 84. NEW YORK, SATURDAY, FEBRUARY 20, 1904. NO. 8.

SPECIAL ARTICLE.

THE ADMINISTRATIVE CONTROL OF TUBERCULOSIS.

BY HERMANN M. BIGGS, M.D.,

OF NEW YORK;

CHIEF MEDICAL OFFICER DEPARTMENT OF HEALTH, CITY OF NEW YORK; PROFESSOR OF THERAPEUTICS AND ADJUNCT PROFESSOR OF MEDICINE IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

WHEN we consider the transcendent importance to the human race of the observations of Koch on the etiology of tuberculosis, and the completeness of his demonstration of the communicable and preventable character of the disease, it seems difficult to understand the limited extent of the sanitary procedures since adopted for its restriction. The imperative demand for the enforcement of comprehensive measures for the prevention of tuberculosis should have been as evident to sanitarians twenty years ago as it is to-day. No facts have been added to our knowledge within this period which are really essential to the intelligent sanitary surveillance of this disease. The universal prevalence of the disease, its infectious and communicable character, its preventability and curability, all of these facts—the important ones bearing on the administrative control—are not of recent discovery. They have not been developed by the agitation of the past few years, but were as manifest to the student of this subject fifteen or twenty years ago as they are now. Very slowly has a partial comprehension of the tremendous significance of these simple well-known facts forced itself on the minds of the medical profession, the sanitary and civil authorities, and the people. But even now, only here and there throughout the civilized world have measures been put into effect looking to the administrative control of tuberculosis. Notwithstanding all that has been said and written, notwithstanding the popular education and agitation, notwithstanding the formation of antituberculosis societies and antituberculosis leagues, notwithstanding the organization of many associations for the erection of sanitoria, and the foundation of institutions for the study of tuberculosis, notwithstanding the measures adopted for the prevention of the disease in animals, still only a very small percentage of the governmental municipal and state sanitary authorities of this country, Great Britain and the Continent have adopted provisions which can be regarded as in any way comprehensive, or effective in dealing with this disease.

If we seek for an adequate explanation for this attitude, it is not after all difficult to find. In speaking of this matter several years ago, Koch said in substance to the writer, "the adoption in Germany of such measures as are already in force in New York City will not be possible until the generation of medical men now in control have passed away. Not until a younger generation has appeared, which has had a different scientific training, and holds views more in harmony with the known facts regarding the etiology of tuberculosis, will it be possible in my opinion to bring about an intelligent supervision of this disease."

The idea has been so firmly fixed in the minds of the authorities and of the medical profession, that administrative control applies only to the more readily communicable acute diseases, like smallpox, scarlet fever, diphtheria, etc., that the inclusion of tuberculosis with these diseases has seemed to them impracticable, and the enactment of suitable legislation conferring power on the authorities to deal with this disease in another way has either not been considered or has been regarded as impossible. In only a few instances have effective measures been adopted, and in these instances, as was the case in New York, the power has usually rested with the sanitary authorities themselves to determine what diseases should come under their surveillance, and under what conditions.

Notification is a necessary preliminary to any plan of supervision, and yet only five years ago a special commission of the Academy of Medicine of Paris reported against a proposition to place tuberculosis in the class of notifiable diseases. Two principal reasons were advanced against the proposition: First it was pointed out that notification involved the divulging of a medical secret, which would be harmful to the patient (this applies of course with equal force to the diseases usually called contagious); and it was furthermore insisted that as the public did not regard tuberculosis as being contagious, or in the same class with the contagious diseases, but considered the disease hereditary, the public would not accept such a legal enactment without protest and resistance. The second reason was regarded as more important and was in effect that in a family unwilling to follow instructions sanitary restrictions would be impossible, as an almost continuous intervention would be required on the part of the sanitary officers for months and years. The only efficient alternative in such cases, it was pointed out, would be the consignment of the consumptive to a hospital, a practice followed in Norway. The Commission concluded that compulsory notification must not be considered, at least at that time.

Sir Richard Thorne, the Medical Officer to the Local Government Board of Great Britain, in the Harben lecture in 1898 on "The Administrative Control of Tuberculosis," after a careful

consideration of the various problems presented under the English law relating to infectious diseases, pronounced definitely against this proposition, on the ground that the hardship to the individual, which would follow notification and the enforcement of proper regulations, would be so great as to render this measure unjustifiable. In the same year the Academy of Medicine of New York, through a special committee appointed to consider the regulations, which had then been adopted by the Department of Health of New York City regarding notification, declared it as its opinion that the procedure was at that time inexpedient and inadvisable. Every important medical society in New York City then expressed even more strongly, than the committee of the Academy the opinion that the action of the Health Board was unwise and unwarranted.

In the action of these and other societies and commissions, and in the opinions expressed by various authorities throughout the world, it has always been evident that they have been influenced by precedents as to the functions of the sanitary authorities, and have felt very strongly the striking difference between tuberculosis and the diseases, which had previously been subject to sanitary control. It has often been pointed out that the so-called contagious diseases are acute, and the whole history of even the most protracted case is comprised within a period of a few weeks, or at most a few months, whereas with tuberculosis, the infectious period usually extends not simply over a few months, but more frequently over several years, and it may comprise half a lifetime.

The contagious diseases usually entirely incapacitate the individual, during the early period at least, and the dangers of the transmission of the infection are so great and the evidence of it so immediate, that no questions can properly be raised as to the justification for proper isolation and supervision. On the contrary, all authorities agree that under proper conditions the consumptive is not necessarily a source of danger, even to his most intimate associates. He may be able to pursue his usual avocation for years. The danger of the transmission of the disease is much less evident, and the source of infection is much more difficult to trace.

The consideration of these and other important points of difference between tuberculosis and the contagious diseases has dominated the situation. It has seemed difficult for the medical or lay sanitary authorities to understand, that with the new knowledge afforded by the observation of Koch and others an entirely different sanitary problem was presented for their consideration, and that for its solution new methods must be adopted. Very gradually comprehension of this simple and apparently quite self-evident fact has forced itself upon them. It may be said, I think, to be now an almost universally accepted fact that some kind of action or supervision is justifiable and necessary, and the only difference of opinion is as to the extent of the measures which should be adopted and as to the manner of their enforcement.

It is my desire in this address to present for your consideration, what it seems to me these procedures should be, and also in part what they are now in New York City. I may say in passing that so long ago as 1887 I had the privilege, in conjunction with the other consulting pathologists to the Department of Health of New York City, of advocating the adoption in New York of measures almost as comprehensive as those now in force, but it was so evident at that time, that neither the medical profession nor the people of the City would approve these measures, that the Board of Health felt their immediate adoption in toto was inadvisable.

What measures then does the efficient administrative control of tuberculosis require?

1. The compulsory notification and registration of all cases is essential. The fundamental importance of this measure is so evident that its consideration seems hardly necessary. It must of course appear at once that unless there is a system of compulsory notification and registration, the enforcement of any uniform measures for prevention is impossible. Practical experience with this procedure has made it perfectly clear that the objections which have been urged against it are without force or foundation.

In New York City in 1893 a system of partially voluntary and partially compulsory notification was adopted. Public insitutions were required to report cases coming under their supervision; private physicians were requested to do this. Under this provision the Department of Health carried on this work for three and a half years, and then adopted in 1897 regulations requiring the notification of all cases. For a number of years, while continuous pressure was brought to enforce this provision, it was not strictly enforced, although more and more complete compliance with its requirements was each year attained.

It has already been said that as tuberculosis radically differs from the more readily communicable diseases usually called contagious, so the measures for the sanitary supervision of tuberculosis must differ from the measures adopted in this class of diseases. This should be the attitude of the health authorities always, in the enactment and enforcement of all regulations. The information contained in the reports of cases should be regarded as confidential information, and action should only be taken by the authorities in those instances, where the conditions require it.

The notification of a case of tuberculosis does not require any action on the part of the authorities, if it seems reasonable to assume that such action is unnecessary. The very fact that tuberculosis is notified by the attending physician as a communicable disease has the greatest educational value, and justifies the assumption in those instances, in which the case is under the supervision of a private physician, that reasonable and necessary precautions for the protection of others

will be taken. If, however, the consumptive has the disease in an infectious stage and is without a home, or is living in a lodging house, or in a poorly furnished room, or in a family in a tenement house, or is receiving charitable medical advice through some public institution, then all objection to the interference or the supervision of the authorities is removed, and in the interests of the public such interference and supervision become necessary. Such is the attitude which has been adopted in New York City. It is assumed and stated positively that in all instances where the consumptive is under the care of a private physican and the latter will undertake to give such instructions as are necessary to prevent the transmission of the disease to others, no further cognizance of the case will be taken by the health authorities after the registration.

The fact should be strongly emphasized again, that the mere fact of notification and registration has in itself a very powerful educational influence. During the year 1902 more than 16,000 cases were reported to the Department of Health in New York City, of which 4,200 were duplicates, and in 1903 more than 17,000 cases were reported.

2. To facilitate the early and definite diagnosis of all cases of pulmonary tuberculosis, the sanitary authorities should afford facilities for the free bacteriological examination of the sputum in all instances of suspected disease. In a large proportion of the cases of early disease the physical signs and the symptoms are not sufficiently definite to permit a positive diagnosis by the general practitioner. An expert may easily arrive at a positive conclusion, but the general practitioner remains in serious doubt. In the absence of a positive result from an examination of the sputum, the attending physician awaits the appearance of more definite signs, and thus too often loses most valuable time, for these more definite signs mean further extension of the disease in the lungs. In some institutions and with many physicians, the positive position is assumed that no case is to be regarded as tuberculosis of the lungs unless tubercle bacilli are found in the sputum. I need hardly point out how erroneous and dangerous is this opinion.

It is of course of vital importance that the diagnosis in every case should be made at the earliest possible moment. A large proportion of the medical profession, in the large cities particularly, have not the facilities, nor are they competent to make such bacteriological examinations. The Department of Health of New York City provided facilities for such examinations in 1894, early in the history of its attempt to exercise control over the disease, and this procedure has proved of very great value to the medical profession, to the sick, and to the authorities. Following the example of New York City, other sanitary authorities have adopted similar measures, and I think it is the general opinion now, that such free bacteriological examinations should be made by

the authorities, and that every convenience and facility for them should be afforded. It is a curious fact in this connection, that large numbers of physicians in private practice who are unwilling or reluctant to directly report cases of tuberculosis, without hesitation send specimens of sputum for examination, with all the facts in relation to the patient which are necessary for registration. It is only on this condition that the examinations are made. During the year 1903 more than 11,000 specimens of sputum were examined in the laboratories of the Department of Health. These specimens came almost entirely from physicians in private practice. There are about 200 depots in New York city where the outfits, blanks, etc., for the collection of specimens of sputum may be obtained and where the specimens may be left for the Department collectors.

3. *Educational Measures.*—It is difficult to overestimate the importance of the duties of the sanitary authorities in the education of the medical profession and of the people on the subject of tuberculosis. Circulars designed to reach different classes of the community and covering different phases of the subject should be widely distributed, and the public press should be utilized to the very largest extent in the diffusion of information. The circulars as issued should be given to the press for general publication. A very important function is performed in this connection by the various lay societies, associations, leagues, etc., organized for the prevention of this disease. By the means of circulars widely distributed through every possible channel, and general agitation in the lay press and numerous and repeated lectures before all classes of the community, a very broad dissemination of knowledge as to the nature of tuberculosis and the means to be adopted for its prevention may be attained. I need not further refer to this phase of the subject.

4. *The Visitation of Consumptives in Their Homes.*—An important part of the work of the authorities consists in the immediate visitation by a physician or trained nurse of every case of tuberculosis not under the care of a private physician or in a public institution as soon as it is reported. At these visits verbal instructions should be given, and printed circulars left for the information of the patient and the family. At the same time data should be gathered as to the history of the sick person and of the family, its social condition and financial income, the number of persons in the family and their wages; the number of cases of tuberculosis which have occurred, the probable source of infection in the individual; the sanitary condition of the premises, the amount of air space for each person, the character of the light and ventilation, the precautions being observed and the possible need of any further interference on the part of the authorities. In the course of these visits it becomes evident in many instances that a patient should be removed to a hospital or sent to a sanatorium outside of the city. In such instances, if possible, the patient should be induced by persuasion to avail himself or herself of such institutional care as seems desirable or available. If the patient persistently refuses institutional care, forcible removal must be resorted to in those instances in which the unsanitary conditions existing render it necessary.

5. The disinfection or renovation of rooms or apartments which have been vacated by consumptives either by death or removal. Trained medical inspectors should be sent whenever it comes to the knowledge of the authorities, that premises have been vacated by death or removal, and proper measures adopted to enforce disinfection of the premises by means of formaldehyde gas, or thorough renovation. In those instances in which the premises are dirty and filthy, and the walls and ceilings are in bad condition, renovation, to be performed by the owners, should be required. If necessary for this purpose, the apartments may be vacated, or if already vacant, the occupation by others must be prohibited until such renovation has been completed. Carpets, rugs, clothing, pillows and mattresses, and any bedding or other textile fabrics, which cannot be properly disinfected by formaldehyde, should be removed by the authorities, and subjected to steam disinfection. Disinfection should be carried out by the health authorities without cost to the occupants or owners, but the cost of renovation, when required, should be borne by the owner of the premises.

A serious difficulty exists in this connection because of the frequent changes of residence of some families containing consumptives; and as the families become constantly poorer on account of the financial loss and expense entailed by the illness, they move continually to a poorer and poorer class of tenements. It is often impossible to trace them, or to obtain information of their change of residence, so that proper disinfection of the apartments may be ensured. The owners of the property may of course be required to furnish information of the removal, but there is danger lest this course may eventually entail some hardship on the poor consumptive in rendering it more difficult for him to find lodgings. This is the most troublesome problem to solve which we have found in New York. I do not feel sure that eventually notification by the owner of the removal of a consumptive will not be necessary, as the only solution of this difficulty.

6. Provision should be made for making repeated visits to cases in tenement houses, when for any reason it has been undesirable or impossible to remove the patient to an institution. These revisits may usually be best made by trained nurses. In this way information may be gathered as to changes of residence, as to the efficiency of the precautions adopted by the consumptive, as to the changes in his physical condition or the financial resources of the family, and as to the necessity of any alteration required in the sanitary treatment of the case.

7. Suitable food, especially milk and eggs,

should be provided by the sanitary authorities or by other authorities having supervision of such affairs in those instances, in which the families are in such destitute circumstances, that proper or sufficient food cannot be obtained by them, and when the patient for any reason cannot be removed to an institution.

Some very difficult economic problems are presented in some of these cases. For example: A family consists of a mother with moderately advanced consumption and five small children; the father is dead; the income of the family from all sources is insufficient to maintain it properly and furnish the mother with suitable food. But the apartments are well ventilated and sufficiently commodious, they are clean and neat, and the mother makes every effort to obey every instruction and heed every suggestion. She insists on remaining with her children, and her presence is necessary to keep the family together. Undoubtedly the mother would be better off in an institution, and thus too the children would be removed to an institution for children, and would be better protected from the danger of tubercular infection. But then the children grow up as institutional children, which is most unfortunate, and, furthermore, there is no sufficient sanitary ground for the forcible removal of the mother. Under such conditions, for the present at least, I believe, the authorities should provide or see that there is provided, such food or other assistance as is required.

If, however, the apartments are dirty and not well kept, or are small, dark, and badly ventilated, or the instructions are not followed and proper precautions are not taken, then the family should be broken up, the mother should be removed to an institution, if necessary by force, and the children otherwise provided for.

No uniform regulations can be laid down for the disposition of such cases, but each one must be considered on its merits, and the ultimate decision in each instance determined after a careful consideration of all the facts.

The authorities should, however, recognize their responsibilities as to the provision in some instances of food, or other assistance, and should have means at their disposal for this purpose. If this assistance is dispensed by other authorities than the health authorities, it should be under the latter's direction and supervision.

8. The sanitary authorities should provide, or see that there are provided, and should supervise, three classes of institutions for consumptives:

Free Dispensaries.—In these free dispensaries medical treatment for ambulatory cases should be provided. These cases should be constantly under the supervision of the district physicians and nurses attached to the dispensary. Where necessary, not only medicines, but food, should be furnished free by the dispensary to the consumptive poor. The dispensaries should also act as clearing houses for consumptives, and should serve as places to which all institutional cases on their discharge from institutions and all poor cases receiving the care or assistance of charitable organizations should be referred for medical care. From this dispensary suitable cases should be referred to either a sanatorium or a hospital, as seems necessary.

Hospitals for the Care of Advanced Cases.—It is not necessary that all the hospitals for the care of advanced cases should be directly under the control of the sanitary authorities, although they should exercise a general supervision over these institutions. It is necessary, however, at least in a very large city, that the authorities should have control of at least one institution with adequate facilities for the care of certain varieties of advanced cases of the disease, which it may be necessary to forcibly remove to the institution and retain there against their will. These are of several types: First. Those which are discharged from other institutions, because they are from the institutional standpoint exceedingly undesirable patients, or because they have violated the regulations of the institution. A moment's consideration will show that the sanitary point of view and that of the authorities of an institution widely differ. In order to maintain the discipline of an institution cases which persistently violate its regulations must be dismissed. From the sanitary standpoint, these are of all cases those which it is specially important should be provided with institutional care. Homeless, friendless, dependent, dissipated and vicious consumptives are those, which are likely to be most dangerous to the community. If not cared for in an institution, they are wandering from place to place, living in lodging houses or sleeping in hallways or wherever cover can be found; negligent as to the disposal of their expectoration, and disseminating infection in every place which they visit. Such cases must be provided for by the sanitary authorities at any cost, and if necessary they must be removed by force to proper institutions and there detained.

Second.—Cases living in lodging houses, or those which are inmates of public institutions not having facilities for their care, who are unwilling to enter any of the institutions, which are available, must be provided for and must be in the same way removed, by force if necessary, and detained.

Third.—It not infrequently becomes necessary in a large city to remove from their homes, cases which are almost necessarily sources of danger to the other members of their family; in those instances in which the sanitary conditions are very unfavorable, when there is great poverty, destitution, or overcrowding, and when the patients themselves are unwilling to enter an institution, the health authorities must intervene and remove such patients by force and detain them.

Fourth.—There are numerous cases which have already been under the care of an institution, and which become for some reason dissatisfied with their care and are determined to return to their homes. In these instances when the family is unwilling or unable to provide properly for

them, the patients should be removed by the health authorities and retained under supervision.

It will be readily understood that the classes of cases, which have been referred to as necessarily coming under the supervision of the health authorities are generally very undesirable and difficult to control. Yet the experience of the Department of Health of New York has shown, that rarely is any real difficulty experienced in the management of these cases, if the accommodations which are provided and the food and care given are of a superior character. It will be readily understood, that the measures suggested here can only be taken, where the sanitary authorities have full power and control, and that patients can be retained only in institutions over which they have direct authority. So far as I am aware the forcible removal of tuberculous patients has not been attempted by any sanitary authorities excepting those in New York City.

Sanatoria.—The sanitary authorities should provide or have available, proper sanatoria in favorably situated country districts for the care of early and incipient cases. No further comments seem necessary on this phase of the subject. It is evident that as the authorities have to deal with both the prevention and care of tuberculosis, such institutions are imperatively demanded. As has often been pointed out, every early case removed to a sanatorium, not only removes the individual who may be for a long period a source of danger to others, but also affords the best chance for recovery. Such patients when cured and discharged from the sanatorium are educational factors of no small moment in the community.

9. The sanitary authorities should issue regulations applicable to public institutions as to the care of consumptives. The admission and treatment of such patients in the general wards of general hospitals should be prohibited, and all public institutions caring for such patients should be required to provide separate rooms or wards. These regulations should apply not only to general hospitals, but also to the hospitals for the insane, to penal institutions, homes, asylums, etc. Suitable regulations should be formulated in regard to cases occurring among the teachers or pupils in the public schools and as to employees in factories, workshops and mercantile establishments, and as to occupations of a nature which are likely to disseminate the disease.

10. The sanitary authorities should enact and enforce regulations prohibiting spitting in all kinds of public conveyances, such as street cars, steam railroad cars, ferry-boats, etc., and on the floors of public buildings and places of public assembly, such as ferry-houses, depots, etc., and in the halls of tenement houses, theaters, in factories, etc. Spitting on the sidewalks should also be prohibited.

The fundamental importance of the careless disposal of sputum in the causation both of pulmonary tuberculosis and the acute respiratory diseases has not been fully recognized, I believe. It seems to me that here is the keynote to the whole question of the prevention of the diseases of the respiratory organs. In various forms of pneumonia as well as in tuberculosis, the causative microorganisms are found in the secretions of the respiratory tract; and when these secretions are not properly destroyed at the time of their discharge from the body, they become more or less widely scattered, dried, pulverized and suspended in the air as dust. Practically all of the organisms causing these diseases belong to the class which do not find favorable conditions for their multiplication outside of the living body, and therefore when they are effective in the causation of disease, it is because they have been derived definitely from some other single case of disease. It is of vital importance in the propaganda for the prevention of tuberculosis and also of pneumonia, that we should educate all classes of the people to a recognition of and a belief in the fundamental importance of the proper disposal of the expectoration and should gradually inculcate the idea that the habit of spitting carelessly anywhere is not only filthy and indecent, but as in many instances to be regarded as almost criminal. When we have educated the mass of people up to this view, so that this habit of spitting will not be tolerated, the chief factor in the solution of the problem of the prevention of tuberculosis will, in my opinion, have been found.

A number of measures of minor importance in the surveillance of the tuberculous diseases have been in operation in New York City. Among these may be mentioned, the semi-annual census of the cases of pulmonary tuberculosis under treatment in public institutions in the city. It has also been the custom during the last two or three years to communicate with the attending physician in cases of tuberculosis, which have been reported through the sputum examination or directly, and to enquire whether the patient is still under treatment, and if so, whether improvement has taken place or not, and whether the physician has any objection to a visit being made to the patient if he or she is not at that time under his observation. If the physician replies that the patient has passed from his observation, and he has no objection to an investigation by the department, an effort is made to locate the patient and determine what the condition is.

Sanitary cuspidors are supplied by the department through trained nurses for the use of patients who are very poor in the tenement house districts, and large numbers of these cuspidors have also been supplied to various charitable societies, which have supervision of, or are extending help to cases of consumption in their homes.

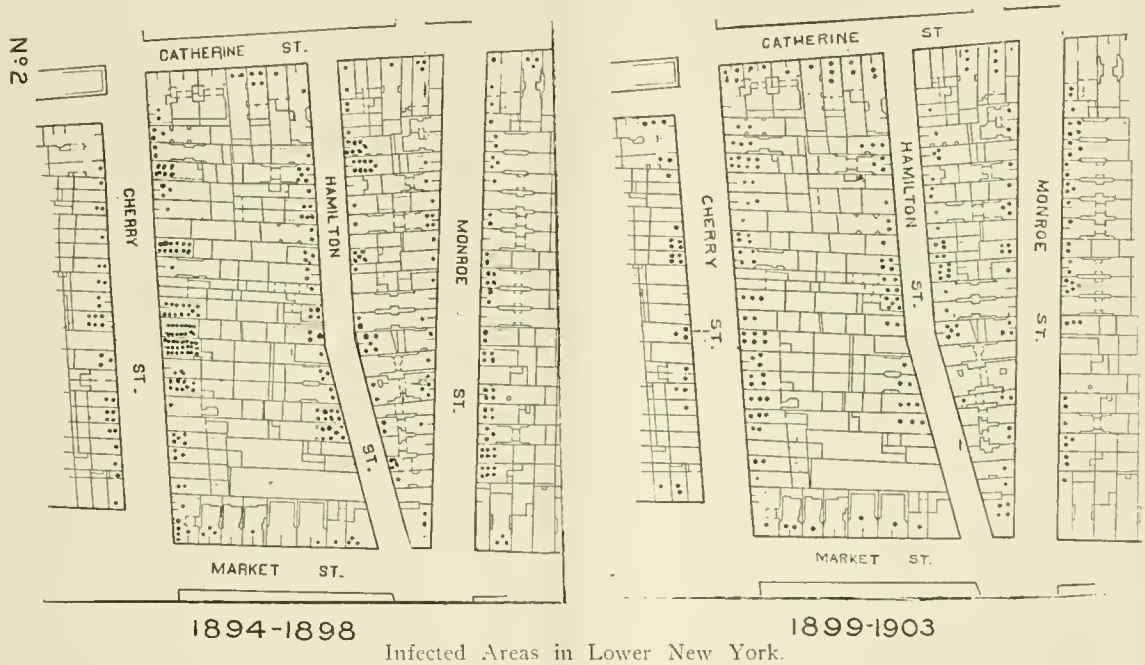
Large numbers of circulars of information have also been supplied to these societies for distribution, and similar circulars in various languages have been furnished to various labor unions for distribution among their members.

The inspectors of the Tenement House De-

partment in the course of their house to house inspection, report to the Department of Health any cases of apparent tuberculosis which they may find and these are investigated by the Department of Health.

In the very beginning of the work in New York, sectional maps of the Borough of Manhattan were prepared showing every house lot in the borough on a sufficiently large scale so that all cases of tuberculosis which came under the observation of the department and all deaths from this disease could be plotted, to show the topographical distribution of the disease. I have had some of these reproduced to show the extraordinary prevalence of the disease in some of the crowded tenement house districts.

Attempts are now being made to secure the condemnation by the city of several areas in the tenement house districts in which tuberculosis has been particularly prevalent.



Infected Areas in Lower New York.

One minor measure which has been found of a good deal of service in New York has been the house to house inspection in tenement house districts by women physicians in the search for unreported cases of tuberculosis. Quite a large number of such cases have been found in this way, especially among the foreign population. It is also of the greatest importance in this connection, that the trained nurses and medical inspectors should know the language of the people whom they are visiting. Great care has been taken, as far as it was possible under the civil service regulations, to obtain trained nurses and physicians who speak foreign languages. We have now engaged in this work, nurses who speak French, German, Yiddish, Russian, Italian and Polish.

These measures as detailed seem to me to include the more important provisions of a scheme for the efficient administrative control of tuberculosis. Several questions arise in this connection: (1) Is such a scheme feasible and practicable? (2) Are there serious objections to the enforcement of the measures proposed? (3) What results may be reasonably expected from the enforcement of such measures?

In answer to the first question—Is such a scheme of sanitary surveillance of tuberculosis feasible and practicable? I would say decidedly, it is. In its main and most important features such a plan has been in force in New York City for a number of years. The feasibility and the practicability have been conclusively demonstrated by an experience in the second largest city in the world. In only a few of the less important details is the general plan as now followed in New York wanting. Referring to these measures specifically, it may be said as to registration, that nearly 13,000 new cases were registered in the year 1903 in New York City; and over 11,000 specimens of sputum were examined. Large numbers of circulars of various kinds designed to reach different classes of the community are being and have been issued each year. During the last year over 100,000 "Circulars of Information for Consumptives and Those Living With Them" were issued by the Department of Health. These were printed in many different languages, for example: English, German, Italian, Yiddish, Chinese, Russian, Ruthenian, Polish, etc.

All cases of tuberculosis reported to the department not under the direct care of a private physician are regularly visited by medical inspectors and trained nurses, and the main facts in regard to the individual, family, sanitary conditions of the premises, etc., are gathered; instructions are given and circulars of information

left. All rooms or apartments which have been vacated by consumptives either by death or removal, so far as the department can obtain such information, are either immediately disinfected, or renovation is ordered and their occupation by others prohibited until the orders are complied with. Carpets, rugs, pillows, mattresses, etc., are removed by the department, disinfected by steam, and returned. Provision is made for continuous supervision of such cases as remain in tenement houses and require such supervision, through trained nurses and medical inspectors.

A special dispensary for the treatment of consumptives has been provided and is just about to be opened by the Department of Health, where it is proposed that treatment, medicines and necessary food shall be furnished free of charge. A series of pavilions have been opened by the Department of Health for the care of those, whom it is necessary to remove by force and detain, such as the undesirable and insubordinate cases discharged from other institutions, and also homeless, friendless and vicious cases.

The Department of Health has appealed to the city authorities for funds for the erection of a suitable sanatorium outside of New York City for the care of incipient cases among the poor, and there is every reason to believe that funds will soon be forthcominig for this purpose.

Regulations have been enacted relating to careless expectoration, and to a considerable extent have been enforced in public conveyances. Regulations prohibiting spitting on sidewalks, in the public halls of public buildings, tenement houses, etc., have not as yet been enforced, although it is proposed to soon adopt more active steps in this direction.

The Department of Health of New York City has not as yet undertaken to provide food or assistance to the consumptive poor living at home, where for any reason they cannot or should not be removed, neither has it undertaken to provide full regulations for the supervision of such cases in public institutions, in the public schools and as regards employees in factories, and occupations in which consumptives are likely to be a source of danger.

Excepting in these respects, the scheme as presented is practically in force now in New York City, the extent and the strictness of the supervision having each year during the last ten years been materially increased. What, therefore, is practicable and feasible in New York should be practicable and feasible in cities of smaller size, and it should be possible to enforce more readily and more satisfactorily similar regulations in them.

As to the second question—Are there serious objections to the enforcement of such a scheme, or are the objections valid which have been urged by some authorities? the reply to this is decidedly in the negative. Very great opposition met the proposition of the Department of Health to undertake this work in the beginning and many difficulties were encountered in the early years owing to this opposition. But experience has shown that the obstacles are largely imaginary; that the harmful results which were predicted as certain to follow, have failed to materialize. Practically no serious difficulties are encountered in carrying on the work. I would say that the difficulties with reference to the work of the department in New York in relation to tuberculosis are really less serious than those encountered in connection with the contagious diseases. There has been hearty approval by the majority of the medical profession, and acquiescence by the remainder.

In answer to the third question—What may be reasonably expected from the enforcement of such measures? we find again an answer in the experience of New York. There has been a more rapid fall in the tuberculous death rate in New York City, than in any great city in the world, and this notwithstanding the fact that the conditions in many respects are much more unfavorable, because of the very dense population in the great tenement house districts of the city and the large element of foreign-born population. It should be remembered that in no city of the world is there such a density of population as exists in many of the wards of the Borough of Manhattan. In numerous districts on the East Side the population varies from 600 to 800 people to the acre, whereas the most densely populated districts of Paris, London, Vienna and Prague have only 400, or less persons to the acre. When this fact is kept in mind, the difficulty in reaching the large foreign born element of the population, which speak their native tongue and retain their native customs will be appreciated.

During the last ten years there has been a decrease of 40 per cent. in the death rate in children under fifteen years from pulmonary tuberculosis and tuberculous meningitis, these being the two forms of tuberculous disease in which an approximately accurate diagnosis is likely to be made. It is precisely in this, the youngest element of the population, that one would first look for definite results from the enforcement of measures for the restriction of this disease. There has also been a decrease in the total tuberculous death rate between 1887 and 1902—a period of sixteen years—of 40 per cent.

A considerable fall in the death rate from tuberculosis has been noted in various countries and cities and it has been maintained and apparently shown, that the decrease was only in small part a real decrease and was accompanied by an almost equal increase in the death rate from the acute pulmonary diseases, notably pneumonia. The claim has been made that there has been simply a substitution in the death returns of pneumonia for tuberculosis. Very great care has been taken in New York City to investigate this phase of the problem and it may be said in the first place, that no corresponding increase has taken place in the death rate from the acute pulmonary diseases. A small increase has occurred since the first great grip epidemic in 1890, but this increase amounts

to only about 10 per cent., and is, I believe, undoubtedly due to the influence of grip in increasing the death rate from the acute pulmonary diseases.

During the last three or four years, at intervals, all of the pneumonia deaths have been compared with the index of tuberculosis cases reported, to determine whether any cases reported as tuberculosis were subsequently returned as having died from pneumonia. This investigation showed a very small number of cases of this kind, not exceeding three or four a week in the Boroughs of Manhattan and the Bronx and subsequent investigation in these, in the majority of instances showed that a reasonable doubt existed as to whether they were tuberculous originally or whether tuberculosis was at all a factor in the causation of death. In addition to this, during the last three or four months, especial detailed investigation has been made of all the deaths reported from pneumonia, occurring in persons over five years of age and not reported by large public institutions. The latter were excluded because it seemed fair to assume that the reports of death from large public institutions could be relied upon as accurate. Some hundreds of deaths of this sort have been investigated, to determine whether the history of the disease as given by the family and the attending physician justified the assumption that death was really due to tuberculosis and not due to pneumonia. The results of these investigations have again shown that in a surprisingly small number of them was there any real reason for assuming that tuberculosis was a factor in the causation of death.

The investigation of these pneumonia deaths is still being continued and in all instances, where the facts justify the assumption that death was due to tuberculosis, the death records are correspondingly changed. As further investigation has shown that nearly 90 per cent. of the deaths returned as due to tuberculosis have been previously reported to the department as suffering from tuberculosis, the conclusion seems to be thoroughly substantiated that the decrease in the deaths from tuberculosis is a real one and not in any material respect merely apparent.

I do not at all intend to indicate that the whole of the reduction in the death rate from tuberculosis in New York City has been the result of the measures directed especially against this disease, for many other factors have undoubtedly contributed to it, but I do believe that the very great and rapid fall in the tuberculous death rate is the direct result of the application of these measures; and I fully believe that the next fifteen years will see a reduction quite equal to that which has already taken place.

If we accept at all the necessary deductions of our scientific convictions in relation to tuberculosis, there can be no escape from the conclusion that tuberculosis is of all the important infectious diseases with which we have to deal, certainly the most preventable. I am not only prepared to accept fully the deductions from the known facts in regard to this disease as to the possibilities in its prevention, but would regard the experience of New York City as furnishing conclusive proof of the truth of this conclusion.

This is the great urgent sanitary problem of the new century. In no other direction can such large results be achieved so certainly and at such relatively small cost. The time is not far distant when those States and municipalities, which have not adopted a comprehensive plan for dealing with tuberculosis will be regarded as almost criminally negligent in their administration of sanitary affairs and inexcusably blind to their own best economic interests.

HOUSE INFECTION OF TUBERCULOSIS.

BY LAWRENCE F. FLICK, M.D.,
OF PHILADELPHIA.

The kaleidoscopic phenomena of this earth, as we see them around us, are the result of a continuous alternation of life and death. In this beautiful panorama death is as necessary as life. Something is always dying that something else may live. Inorganic matter continuously is being changed into organic matter and organic matter into inorganic. For changing organic matter into inorganic matter God has created the microorganic world.

A microorganism which perhaps has slipped away from its natural place in organic nature and in consequence has done much damage to man is the tubercle bacillus. In the great division of organic matter it generally is credited to the vegetable kingdom. In a classification of microorganisms it is technically known as a facultative saprophite. By this is meant that ordinarily it gets its living as a parasite on some higher organism but that it may subsist on dead organic matter as a saprophite. In a subclassification of microorganisms it is known as a faculative aerobic parasite. By this is meant that ordinarily it grows in a tissue from which air is excluded but that it may grow in some substances, under certain conditions, in the presence of air.

When the tubercle bacillus grows in the tissues of a human being or of an animal it gives rise to a condition which has forcibly arrested the attention of man because of the suffering, sorrow, and misery which accompany it and follow in its wake. In the early history of medicine this condition was named phthisis and consumption. In more recent times it has been divided into two epochs; the earlier being called tuberculosis and the later consumption. In earlier times, too, the condition was viewed by mankind generally as a providential visitation, the punishment for sin, touching not only the immediate offender but reaching the offspring to the third and fourth generation. Science has demonstrated that it is a mere episode in nature subject to natural laws and absolutely under the control of man's will.

Man is interested in tuberculosis because it is a disease. The same processes and phenomena in other fields of nature give pleasure to man but here they give discomfort and are followed by sorrow and misery, because man himself is the field of operation. The word disease means want of ease. Quite naturally man has given much thought to how to avoid getting tuberculosis and how to get rid of it when it afflicts him. By reason of his superior intelligence, man has always been able to control his organic foes so far as visible objects are concerned, but in his fight against the microorganic world he is confronted with a much more serious problem. Much has been done, however, to throw light upon this newly discovered enemy and already it is demonstrated that man need no longer get tuberculosis and that if he is so unfortunate as to get it he need not die of it. Unfortunately the knowledge which makes this new dispensation possible is still in the hands of a few.

All diseases which are caused by microorganisms are communicable. This is a self-evident proposition. Whatever is living can only come from a parent and phenomena which are due to the growth and development of living organisms cannot arise except by reason of the growth and development of these organisms. There is a difference, however, in the manner in which parasitic microorganisms are conveyed from one person to another. Some are conveyed through the instrumentality of insects, some by means of water, and others by contact, direct or indirect. Some parasites have two kinds of hosts, a major and a minor host: some can reproduce themselves outside of a host; and others always remain dormant when out of the host. Parasites which have two hosts and parasites which can reproduce themselves outside of a host may be conveyed from one person to another over long distances, while parasites which are conveyed by contact can only be conveyed within a limited circumscribed environment. The yellow fever parasite, for instance, is conveyed through the mosquito; the typhoid fever parasite through water; and the tubercle bacillus by contact.

All diseases which are conveyed by contact are termed contagious. Contagious diseases are not necessarily alike, however. There may be a great difference in the intensity of contagion. The acute contagious diseases are much more intensely contagious than the chronic contagious diseases. In principle the contagion of all is the same, but in practice the method differs widely. Smallpox, measles, and scarlet fever, for instance, are contagious in exactly the same sense as tuberculosis, so far as the principle is concerned, that is, they are conveyed by contact, but the intensity of the contagion is so much greater with them than with tuberculosis that practical measures for the prevention of the former would in no sense apply to the latter. Smallpox, measles, and scarlet fever affect the whole body and contagion is rapidly given off from the entire body; tuberculosis is a local disease and contagion is given off from one or two points only. In smallpox, measles, and scarlet fever the matter which carries the microorganisms may be invisible; in tuberculosis it always is gross and easily seen. In smallpox, measles, and scarlet fever places and things soon become intensely contaminated: in tuberculosis it takes a long time to produce such a result. Intimate association, therefore, with a person suffering from smallpox, measles, and scarlet fever without contracting the disease is impossible unless the person thus exposed has an immunity from vaccination or previous attack, while intimate association with a consumptive without contracting the disease is quite feasible.

The contagion of tuberculosis, indeed, is of a kind by itself. It differs somewhat from the contagion of every other disease of which we have knowledge. It is so unique that writers have had some difficulty in finding an epithet descriptive of it. This is the reason why many writers object to calling tuberculosis contagious. Some would have us call it communicable, but this term is too generic. Others have suggested the epithet infectious for it, and this does not fit at all because it has a specific meaning which only applies to such diseases as malaria and yellow fever.

The most striking feature about the communicability of tuberculosis is that it depends almost entirely upon the house. An enclosure of some kind is so necessary for the conveyance of the disease from one person to another that contagion is impracticable without it. It is therefore with good reason that we use the phrase house infection of tuberculosis, when we speak of the practical manner in which the disease is spread in a community. The word infection, of course, is used in the broad sense of conveyance and the word house in the broad sense of an enclosure. The phrase tells pretty nearly the whole story of the communicability of tuberculosis and covers the entire proceeding from the beginning to the end,—garnering the seed, preparing the soil, implantation, rearing the tender plant, nurturing the full-grown shoot, maturing and harvesting.

The house is the depository of the tubercle bacillus outside of its host. Were it not for the house, the tubercle bacillus would soon have to perish from the face of the earth. It could not be preserved. Sunlight, air, and water are its natural enemies. The water dissolves it out of its caché and the sunlight and air destroy it. How long tuberculous matter may remain vital in the open air has not been definitely determined, but all agree that the time is very short. Even when the bacilli in such matter are not killed they are weakened so that they will not readily take root when planted. In the house, on the contrary, tuberculous matter may remain vital for a long time because it becomes dry and the broken-down tissue serves as a caché for the bacilli. Even when the matter becomes finely

pulverized, so that the bacilli no longer have so much protection, it remains vital for a long time because the sun and air cannot get at it.

Ordinarily the tubercle bacillus is dependent upon other microorganisms for its exit from its host. These are the streptococcus and the staphylococcus. They are pus-producing organisms and are very adept at destroying tissue. When they join forces with the tubercle bacillus they kill and soften the tissue which has been invaded by the tubercle bacillus and then nature casts it out. A double purpose is served in this way, the tubercle bacillus is helped out of its host and is given a protective covering toward preservation while out of the host. The broken-down tissue which is thrown out forms the protective covering.

In the transition of the tubercle bacillus from one host to another we have a beautiful illustration of nature's jealous care of every form of life. The tubercle bacillus is a motionless helpless microorganism, which can grow and reproduce itself only under certain conditions, in a definite soil, and which requires during the interim between its exit from one host and its entrance into another, special protection, and, for admission into a new host, special opportunities. These are secured for it indirectly through its toxin and the toxins of its associates. By sensations set up in the nervous system, it lures its victim into the very place where exist the best conditions for the preservation of its species, and the best opportunities of finding a new host. Consumption is the autumn of tuberculosis, the blossom grown into ripe fruit. When it comes on the victim, by reason of his chilliness, malaise, and general feeling of helplessness, seeks shelter in some enclosure and is deluded with the idea that the farther he can get away from sunshine and fresh air the better are his chances of recovery. The house thus becomes the harvest field of the ripe tubercle bacillus and the seed quite naturally falls into the very place which by nature is intended for its depository.

The house also prepares soil for the tubercle bacillus. We have every reason to believe that the bacillus cannot get a foothold in perfectly healthy, normal tissue. It is quite likely, indeed, that primordially the tubercle bacillus was a saprophite only and that its function in the world was to change dead organic matter into inorganic matter. It is easy to conceive how gradually it may have evolved into a parasite by growing on tissue, which while not dead was much debased. At any rate, even at the present time it does not seem to be able to invade tissue until the tissue has been injured in some way either by malnutrition, by traumatism, or through the agency of some other microorganism. Malnutrition is one of the most common predisposing causes of tuberculosis.

The physical life of man and animals is a chemical process. There is a combination of certain elements through the instrumentality of a living cell with evolvement of beings endowed with life. Food, air, and water are the substances used in the process. In proportion as these substances are at hand in proper quantities the being evolved is a healthy one; and in proportion as any of the substances are deficient or defective the being is an unhealthy one. Of the three substances required in this chemical process, air is perhaps the most important, and certainly the most necessary. Life may be maintained for some days without food and water, but for a few minutes only without air. The same is true of health. A person may keep fair health on a stinted supply of food and water for a long time but soon succumbs to a stinted supply of air. This probably is due to the fact that air plays a double rôle in health. It not only carries in oxygen for chemical purposes but it carries out poisonous products of chemical action. It is believed by some that rebreathed air produces soil for the tubercle bacillus more through poisonous products of combustion which are disseminated in the air than by reason of deficiency of oxygen. Probably it does it by both. At any rate, housed human beings and animals are very prone to tuberculosis. Deficiency of oxygen certainly leads to malnutrition. Too much food and too little air not only lead to defective metabolism, but throw upon the organs of the body poisonous products which must be gotten rid of to the detriment of the whole system.

Implantation of the tubercle bacillus is greatly facilitated by the house. For implantation prolonged intimate contact with a person, place or thing which has been intensely contaminated with tuberculous matter is necessary. The mere presence of a few tubercle bacilli is not sufficient. Everybody has some resisting power to tuberculosis and with everyone there is a minimal dose which will give an implantation. No doubt this dose differs with different people, but the resisting power exists to some extent in everyone. Even in inoculation experiments on animals a minimal dose has been found below which injections prove negative. This minimal dose, in a sense, measures the individual's fighting capacity against the disease. So long as the minimal dose is not reached an implantation cannot take place. Frequent warfare against a dose below the minimal dose increases the resisting power of an individual and raises the minimal dose. With animals the minimal dose which can give an implantation gradually can be increased until almost complete immunity has been established.

Experiments upon animals have been made by inoculation. It is quite probable that by the natural mode of entrance of the tubercle bacillus into the system the minimal dose is larger than by inoculation. The natural mode of entrance is by the alimentary canal or the respiratory tract. At both of these ports of entry there is strong opposition to admission. The gastric juice has some germicidal powers and all

along the respiratory tract there are devices for keeping out microorganisms. Beyond the ports of entry lie the lymphatics and the lymphatic glands and beyond these the phagocytic bodies of the blood, all of which wage war against microorganisms that may pass the ports of entry. From what has been done experimentally on animals and from what we have been able to observe clinically on man we have good reason to believe that the minimal dose of tubercle bacilli necessary for an implantation by the natural mode of entrance is quite large. This is not a mere speculation either. Out of every five people who are intimately exposed to the contagion of tuberculosis for a long period of time under the most favorable conditions for implantation only one person develops the disease. This shows that implantation is exceedingly difficult even under most favorable circumstances.

An enclosure is the one place in which contamination with tuberculous matter can become sufficiently intense to create an environment capable of overcoming the resisting power of man and producing an implantation. It is only in a house that vital tuberculous matter can accumulate. In the open air, water, sunlight, and air devitalize it nearly as rapidly as it is given off. Tuberculous matter ejected in a house, unless immediately devitalized artificially, dries and is distributed about in particles varying in size from big chunks to impalpable dust. In these particles the bacilli are cachéd and preserved. Gradually all the particles are reduced to dust either by trituration, oxidation, or the action of saprophites. This tubercle-laden dust settles on the walls, on furniture, and on everything in the enclosure. In the course of time there is quite an accumulation of vital tuberculous matter in such an enclosure and every time the air is disturbed tubercle-laden dust is set in motion. Here then finally is an environment capable of giving an implantation of tuberculosis. Occupancy of such a room means constant inhalation and frequent deglutition of tuberculous matter. Tubercle bacilli continuously find their way into the system and it is only a question of time when more have gained entrance than can be successfully withstood by the guards and disease fighters of the body. The result is implantation of tuberculosis.

The kind of house which offers the best environments for implantation of the tubercle bacillus is first the home, and second the workshop. The home, of all places, is the most prolific of new implantations of tuberculosis. It was on this account that in bygone days tuberculosis earned for itself the reputation of being an inherited disease. Tuberculosis is a family disease. It can most easily be implanted around the hearthstone. It follows the family tree in its distribution and when it once gets into a family it follows that family in all directions until it either has exterminated the family or has exhausted the soil and has made what is left of the family immune. The part of the home in which implantations most frequently take place is the bedroom and next to the bedroom, the dining room. The bedroom usually is the place where the victim of tuberculosis spends his last weeks or months, a period during which the disease is most intensely contagious. Among the poor, the dining room often is used as a bunking place for the stricken one until a day or two before death. Under such circumstances the dining room becomes very much contaminated, and becomes a prolific source of new implantation.

The workshop is a very common means of spreading tuberculosis. By workshop, of course, is meant any enclosure in which one or more people are employed. Tuberculosis is an extremely chronic disease and usually runs a long course, even in its contagious form, before its victim is incapaciated for his usual occupation. Some people work with a contagious form of tuberculosis for the greater part of a working lifetime, occasionally being thrown out of employment for a few weeks or months on account of an exacerbation and again returning with as much vigor as before. Unfortunately, habits of men and women in the matter of spitting, make it easy for a consumptive to contaminate his immediate environment in a shop if not the entire shop. One consumptive perhaps cannot contaminate a large shop so as to produce an infectious environment of the entire shop but he can produce an environment around his own stand capable of implanting the disease in one or more of those next to him, and before long he has associates in the task of polluting the shop. In a workshop in which a case of tuberculosis exists careful investigation will reveal the presence of other cases in various stages of the disease. Deaths will occur from such a shop at regular intervals for an indefinite period so long as the shop is permitted to remain contaminated.

Enclosures such as hotels, churches, public halls, places of amusement and public conveyances, in which people stop for a short time only are not apt to give rise to many implantations of tuberculosis for two reasons. First, a consumptive rarely remains in them long enough to produce a contagious environment capable of giving an implantation, and secondly, healthy people seldom remain in them long enough to get an implantation. There is some danger of contracting the disease in such places for people who are employed in them in the capacity of cleaners and caretakers; but for the casual visitor practically there is no danger.

Things which have been intensely contaminated by having been used for a long time by consumptives may give the disease to others when kept or used indoors. In the open air they may be harmless unless worn upon the person. Contaminated furniture, carpet, and hangings of various kinds when taken into a perfectly sterile house may themselves contaminate the house sufficiently to create an environment capable of implanting the disease. The tuberculous matter

adhering to such articles is distributed about and settles on walls and floors. In the open air, on the other hand, tubercle-laden dust from such articles is apt to be dispersed and scattered about over such a wide area as to make it impracticable for any one person to get enough of it to give rise to an implantation.

The house nurtures the tuberculous growth when an implantation has taken place. Mere implantation of the tubercle bacillus does not necessarily mean a development of a full-fledged tuberculosis. The disease always begins in a very small way and attracts practically no attention. The first crop develops and runs through its course and a second follows, perhaps, a little larger than the first. This is followed by a third and a fourth, each a little larger than the preceding one and thereafter another larger still, until finally so much tissue has been invaded and destroyed as to make death inevitable. At any time during the progress of the disease prior to the destruction of tissue essential to normal functions of the body the economy has within itself the power of throwing off the disease. Autopsies prove that this often is accomplished by nature, unaided by medicine. It probably would be accomplished in all cases were it not for the house.

In the beginning of the tuberculous process the tendency to recovery is so great that the slightest aid to nature may turn the tide toward recovery. The process by which recovery takes place probably is healthy metabolism, that is perfect change of food into tissue. Implantation has taken place because the individual temporarily has been a little below par as result of improper food, insufficient air, overwork, dissipation, an attack of some other disease, or some such matter, one or all. Under proper conditions the implantation is rooted up before it can grow into tuberculosis. All that may be needed is a little rest, a little extra food, and a little more fresh air. In some cases recovery might take place if a little rest could be had even without extra food and air; in others, if better food could be had even though no rest could be taken and the air supply could not be changed; but in all recovery would almost surely follow a life in the open air in spite of bad food supply and overwork. Life in the open air enables one to digest coarser food and do more work without fatigue than is possible indoors. This is probably due to the fact that in the open air the poisonous products of combustion are promptly removed from the system and thus are prevented from embarrassing the entire organization. To cure tuberculosis we must have perfect metabolism, and this we only can have when enough fresh air is taken into the system night and day to oxidize the food and cleanse the blood. Imperfect metabolism predisposes to tuberculosis by debasing the tissues and making soil for the tubercle bacillus.

House life undoubtedly plays an important rôle throughout the entire course of tuberculosis to its culmination in consumption and death. With every recurring crop of tubercle the organs of the body become more embarrassed and the economy is less able to carry on the warfare against the disease. When the disease is in the lungs, as it frequently is, the air supply grows less with each destruction of lung tissue. Fortunately nature has given all air-breathing creatures ample lung capacity, enough and to spare, so that a great deal of lung tissue may be destroyed without interfering with the functions of the body, provided the air supply is right. Under these circumstances other organs, no doubt, supplement the lungs in their functions of elimination. Everything hinges upon an ample supply of fresh air, however. When this is at hand healthy metabolism may be attained even when the disease is advanced and through this health may again be reached. Tuberculosis makes its progress because its victim is shut up in a house where he cannot get fresh air. Unfortunately for the poor an ample supply of fresh air is impossible. Their houses, their homes as well as their workshops, have been constructed on a mistaken idea that whatever shuts out air, heat, and cold is conducive to health. The large death rate from consumption really must be ascribed in a great measure to bad ventilation in home and workshop.

The last scene of conflict between the victim and his foe is the house. Tuberculosis develops into consumption because of the house. This does not mean that people could not get tuberculosis if they lived out of doors, for birds of the air and animals of the field get the disease. Tuberculosis, however, in itself would seldom prove fatal. Both animals and human beings may go through life with tuberculosis and reach old age without being seriously inconvenienced by it. Many animals and people do. Dr. Trudeau has shown by experiments on animals that life in the open air greatly retards the development of tuberculosis and promotes recovery. Rabbits which he inoculated and penned up died, while rabbits which he inoculated and permitted to run at large maintained good health, although they developed tuberculosis. In sanatoria where consumptives are made to live out of doors, wonderful improvement sets in even when the case is incurable. Frequently all the symptoms of consumption disappear and the patient becomes comfortable even when so much tissue has been destroyed that recovery is physically impossible. In other words even consumption in the open air loses all its most serious symptoms. The house makes and maintains consumption, and consumption kills.

Consumption may well be termed a house disease. Without the house it would not exist. It depends upon the house for its implantation, propagation and for evolution of all its phenomena. The house is the place where the tubercle bacillus lies dormant in wait for its new

host; it is the place where the new host gets his implantation; it is the place where the tuberculous subject gradually becomes a consumptive; and it is the place where the consumptive dies.

In studying the progress of civilization in the light of modern science one is struck with the egregious blunders into which man has been led by his desire for privacy and comfort. He has built his house to keep out his enemies, to protect himself from heat and cold and to screen himself from the curiosity of his neighbor. He has sought to make his home his castle but in reality he has made it the place wherein he courts death.

If man desires to free himself from the great white plague he will have to retrace his steps from some of what he considers advanced points of civilization. He will have to learn among other things that fresh air is God's greatest gift on earth and that whatever shuts out fresh air, shuts out health and happiness. In house infection he will find the key to the entire problem of stamping out tuberculosis.

CASE OF TETANY.*

BY JOSEPH BARSKY, M.D.,
OF NEW YORK;
ADJUNCT VISITING PHYSICIAN TO THE CHILDREN'S WARD, BETH ISRAEL HOSPITAL.

The patient is eleven months old, the second child of healthy parents, who do not at present and have not at any time suffered from any nervous trouble. The child was fed on mixed food, that is, in addition to the mother's milk she received cow's milk and, occasionally, food from the table. Patient had not as yet had any exanthematous disease, but contracted pertussis when two weeks old, which lasted until her sixth month. The child did not suffer in general health during that time. In the month of July she had diarrhea for a few days from which she made a complete recovery. The present illness began suddenly on September 15. The mother put the child to bed on the previous evening at the usual hour. She told me that before going to bed it was lively and playful, more so than usual, and slept the entire night without waking: in the morning when the mother looked at the child she noticed that it woke up with a start, its eyes became fixed and staring, and after a few seconds it began to cry. When the mother stepped to take the child in her arms, she noticed that it was rigid, "like a stick." A next door neighbor pronounced the child well: "She is only teething." Toward the evening, as the child grew worse, I was called in "to cut the baby's teeth."

I found the infant stretched out on a pillow, unable to move, and crying at the approach of any one, apparently afraid of being touched. Examination elicited the usual symptoms of tetany, which, in the main, are muscular rigidity and contractures, affecting first the upper and then the lower extremities. The fingers were flexed at the metacarpophalangeal joints. The phalangeal joints were extended, the thumb adducted and extended, and the hollow of the palm deepened; the wrist flexed to almost an acute angle, the elbow-joints rigid and flexed, the shoulder-joints, however, were not involved. Next to the hands the feet are the parts most often affected, as was the condition in this case. The thighs were adducted, there was in this case extreme extension of the ankle-joints, and the toes were flexed so that the plantar surfaces were more arched and deeper than in a normal state. The knee-joints were rigid but the hips were not involved. Pulse and respiration were rapid and temperature 102° F. It is characteristic of the disease that it is always bilateral, with symmetrical contractions, some time of variable intensity on either side.

Trousseau's sign, which is a constant pathognomonic symptom of the disease, may be elicited in the following manner: when an elastic band is applied around the arm thereby compressing the blood vessels and nerves supplying the parts, the hand will at once pass into a tetanic state. This is not due to mechanical pressure alone for the other side will also exhibit the same phenomena. The muscles of the face respond to mechanical irritation very readily. The etiology is obscure, age given by some authors as from six months to two years. Dr. Sachs, of New York, who made an extensive review of the literature of the entire subject, declares this affection as most frequent at the ages of sixteen and thirty-five years. Boys are more often affected than girls. Gastro-intestinal disorders seem to be the main etiological factors in the recorded cases, but in the present one the tetany seems to have been the symptom ushering in an acute bronchitis, which lasted four days and from which she made a complete recovery. Another case seen by me, where tetany was the ushering in symptom of lobar pneumonia, was in a child of eighteen months that died subsequently on the eighth day of the disease.

I would reasonably assume from the above two cases that tetany is not always a complication, as some authorities claim it to be, but that it may be the initial symptom of any of the acute febrile diseases, just as convulsions occur at the beginning of many ailments. It may also be a complication of the many exhaustive diseases, such as typhoid, summer diarrhea or bronchopneumonia. The treatment is purely symptomatic. If the cause is discovered such as intestinal toxemia, or tapeworm, it should be removed, if possible, by proper medication. For the rigidity, I know of nothing better than a warm bath.

Pain is relieved by applying cold to the joints involved and the internal administration of the bromides and antipyrin. In the usual case this is all that can be done. In those rare instances, however, where the respiratory muscles are affected, and life is threatened from asphyxia, chloroform inhalations should be given.

203 East Broadway.

TWO CASES OF SEVERE X-RAY NECROSIS, PRESENTING SOME UNUSUAL FEATURES.*

BY CLARENCE EDWARD SKINNER, M.D., LL.D,

OF NEW HAVEN, CONN.;

PHYSICIAN IN CHARGE OF THE NEWHOPE PRIVATE SANITARIUM, NEW HAVEN, CONN.; MEMBER AMERICAN MEDICAL ASSOCIATION, AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION; SOCIETE FRANCAISE D'ELECTROTHERAPIE ET DE RADIOLOGIE, ETC.

DURING the past two years our attention has been forcibly attracted, and more or less exclusively occupied, by the gross, general, therapeutical influences of the X-ray. The present time, however, is bringing with it a demand for special knowledge concerning these influences, and their evolution, modus operandi and detail, constitute fruitful fields for future research. Clinical observation will designate the problems; physiology, pathology and physics must solve them. The cases following suggest some queries and food for thought in this connection.

Case I.—The first was observed upon a woman fifty years old, of the brunette type, who was under X-ray treatment for pseudoleucemia accompanied by a large accumulation of fluid in the abdomen. The glandular enlargements were very prominent in the abdominal cavity particularly on the left side, and in the cervical, axillary and inguinal regions. The X-ray applications were all made to the abdomen, the tube focused about two inches to the left of the median line, but so arranged that all of the regions affected received some of the radiance. No shields were used except over the face and only a thin towel was interposed between the skin and the source of light. The tubes used were of the German type with divided anodes, forced back a spark of from four to eight inches, and produced rays of high penetration; distance of anode from patient's skin, ten inches; time of exposure, fifteen minutes; exciting apparatus, twelve revolving 32-inch plate Morton-Wimshurst-Holtz influence machine for the first three months, and a sixteen revolving 32-inch plate machine of the same type thereafter.

From July 26, 1902 to December 4, 1902, she received 50 X-ray treatments, being an average of one every 2.6 days. From December 4, 1902 to April 3, 1903, she received 25 treatments, an average of one every 4.7 days, or about half as frequently as during the preceding period. At this time her disease had improved to such an extent that it was considered safe to interrupt the treatment for a while, which was done. During the period that she was under the above-described treatment the skin over the exposed region of the abdomen had repeatedly become heavily pigmented and peeled off exposing healthy pink skin underneath. Twice there appeared a slight erythema with itching and burning, which subsided completely in five or six days upon suspending the applications. As far as the effect of the X-ray was concerned everything seemed to have eventuated most happily up to that time.

I was asked to see her again April 30, and found her suffering severely with sharp cutting pains in the anterior abdominal wall and streaking up under the ribs nearly to the shoulders on both sides. The skin of the abdomen had been darkly pigmented but now a dusky redness showed through the brown, over an area of about six inches in the vertical by ten in the lateral diameters, and a very intense burning sensation was torturing the patient constantly. Various ointments and lotions were applied without securing relief, and it became necessary to resort to morphine in a day or two. The condition progressed from bad to worse, until May 13, at which time an area four inches in the vertical by eight in the lateral diameters presented the typical picture of white gangrene, the dead tissue being yellowish-white in color, of a tough and leathery consistence with the characteristic gangrenous odor. Severe shooting pains were present almost constantly and manipulation of the parts provoked paroxysms of the same lasting for several minutes. Pulse ran from 105 to 115 beats per minute, the temperature varied from 100° to 102° F. and the patient was unable to leave her bed because of the severe general prostration. Her appetite was excellent and continued so throughout the entire course of the illness.

From this time on the dressing consisted of irrigation with normal saline solution followed by a 10 per cent. aristol and lanolin ointment twice daily. At this time also the edges of the slough began to separate and this process progressed steadily until June 9, when it was completed by the exfoliation of the central mass which was three-quarters of an inch thick by actual measurement. Synchronously with the completion of the sloughing process was observed cessation of the sharp, shooting pains, and they did not recur. The edges of the ulcer had begun to heal as soon as the separation of the slough commenced but this process was very sluggish and unsatisfactory and on July 9, 1903, I commenced using the direct electrical current, negative polarity, 75 volts and 5 to 10 milliampères for ten minutes, applied through a bare metal electrode in direct contact with the ulcerating surface, three times weekly. This hastened the healing process very noticeably and the ulcer was completely covered with healthy skin by October 1, 1903.

By the middle of July the epithelial layers of skin covering the apparently healthy areas contiguous to the ulceration and which had been deeply tanned by the rays, had peeled off entirely, leaving exposed newly formed, epithelial layers, pink, soft, and entirely normal in appearance. Two weeks later this tissue had become pigmented and by the middle of September it was as deeply browned as was that which had exfoliated. At this time there was also observed, scattered over this newly-formed cuticle, 25 to 30

* Read at the Fourth Annual Convention of the American Roentgen Ray Society, at Philadelphia, Pa., December 9 and 10, 1903.

wartlike excrescences, varying in size from a mere point to five or six times as large as a pin head. In this connection I should like to call your attention to the fact that no exposures to X-rays had taken place for more than five months preceding, and that since the last exposure the epithelium which had borne the brunt of the treatments had completely exfoliated, its place having been taken by newly formed tissue, apparently unmodified in structure.

Early in September, or five months after the last X-ray treatment had been given, the skin began to break down at a point three inches to the left of the median line and the same distance above the superior border of the original area of ulceration, and spread over an area of three by five inches during the next month. This area became one of typical white gangrene almost at once but did not extend more than one-third of an inch in depth. The management used upon this spot consisted of saline irrigation twice daily, followed by dusting with a powder consisting of equal parts of anesthesine and talc, which controlled the pain perfectly. About half of the slough has now completely separated, leaving a healthy granulating surface, which is slowly healing. I shall apply the direct electrical current for its accelerating influence upon the reparative process as soon as the rest of the necrotic tissue has exfoliated.

The noticeable features about this case are as follow: (1) The depth to which the original necrotic process extended; (2) the "tanning" and excessive proliferation in spots, of the epithelium of the new skin that was exposed by the peeling of that which had been browned directly by the ray, which new epithelium had not been exposed to the ray and was apparently entirely normal in color and structure when it first developed; (3) the cessation of the pain as soon as the necrotic tissue had completely separated; (4) the favorable effect of the galvanic current in hastening the healing process after the necrotic tissue had sloughed off; (5) the appearance of an area of necrosis five months after the last X-ray application, in a region which had prevously exhibited no evidences that such injury had been inflcted; (6) the happy effect of the anesthesine and talc mixture in relieving the pain of this last mentioned ulceration.

Case II.—The second patient, a medium blonde with gray eyes and dark brown hair, aged forty-nine years, came to me for X-ray applications to an inoperable malignant process in the neighborhood of the left broad ligament accompanied by marked ascites, on January 27, 1902. From that date until April 4, 1903, she received 115 X-ray treatments, an average of one every 3.7 days. The technic was the same as had been used in connection with Case I, except that the twelve-plate static machine was used upon this patient for the first nine months. At this time her condition as regards improvement was such that it was considered safe to discontinue the treatment tentatively. While undergoing the treatment the skin over the exposed region had repeatedly become heavily pigmented and peeled off exposing underneath, soft, pink, new skin. Three times there had obtained slight erythema with itching and burning which had subsided kindly upon suspension of the treatments. When the final treatment was given on April 4, 1903, the skin was deeply tanned and felt to the touch dry and brawny, and this latter characteristic seemed to extend for some distance into the subcutaneous tissues.

There was nothing apparent in the condition to indicate that a dermatitis was about to manifest itself, not even an erythema, but there was present at this time a phenomenon that I had never before observed in this connection, consisting of a subcutaneous effusion of blood about as large as a nickel five-cent piece, two inches to the right of the median line and about an inch above the level of the pubis. This area was slightly depressed below the level of the surrounding tissue, was slightly sensitive to the touch, and had developed suddenly two or three days before.

The spot became more and more sensitive. In a few days sharp pains appeared in this region and streaking upward to the ribs, which increased in severity until by May 1 they had become pretty constant and so severe that the internal administration of opiates was demanded, and the area defined by the subcutaneous effusion of blood had become gangrenous. The body temperature ranged from 99.5° to 101° F. and pulse from 95 to 105 beats per minute. The necrotic area gradually increased in size until by the middle of May it was as large as a silver dollar. At this time another hemorrhagic effusion as large as a silver quarter of a dollar appeared on the left side of the median line which became necrotic about the first of June. By the first of July these areas had coalesced at their lower borders through an isthmus three-quarters of an inch in width, the necrosis having been preceded by little scattered subcutaneous effusions of blood as had been the case with the other lesions. The affected regions were covered by the same tough, malodorous, yellowish, fibrous tissue described in connection with Case I, and had at this time reached their maximum size, consisting of a circular spot on the left side two inches in diameter, and on the right side an irregular spot two inches in the vertical and three in the lateral diameters. As I have just stated these areas were connected at their lower borders by an isthmus of necrotic tissue three-quarters of an inch in breadth, which dimension subsequently increased to one and one-half inches.

By this time the epithelial layer of the skin covering the adjacent, apparently uninjured regions and which had been deeply tanned by the rays, had exfoliated and the newly formed tissue which took its place was normal, soft, and pink in structure and appearance. In a few days, although no exposure to X-rays had taken place, it became

harsh, dry, and profoundly erythematous with considerable itching, but showed no fresh pigment deposits, and has remained in that condition ever since.

The long-continued severe pain had greatly impaired the patient's general condition and she was admitted to the sanitarium, where she could be more efficiently treated, on July 8, 1903. To make a long story short, we ran through the list of pain-relieving applications, including the anesthesine and talc mixture, which, by the way, made the pain worse in this case, and none gave any satisfaction except the ice-cap placed over the ulceration, and an ointment consisting of lanolin with enough olive oil to soften it and ten per cent. of powdered opium. The application of this twice daily preceded by saline irrigation was the management finally adopted.

I used the galvanic current as with Case I, in the hope that it would hasten separation of the necrotic tissue but without result, and the necessary manipulation of the parts was so painful to the patient that the procedure was finally abandoned.

The sloughing of the necrotic tissue progressed very slowly and was not complete until early in October, but the disappearance of the last fragment was accompanied as in Case I, by the disappearance of the severe pains. The necrosis extended to the depth of about three-eighths of an inch and a healthy granulating surface was left which is healing very satisfactorily under applications of the direct electrical current, as described in connection with Case I, which I began using five weeks ago.

Early in October, or six months after the last X-ray treatment had been given, there appeared another slight subcutaneous hemorrhage the size of a dime, three inches to the left of the median line and two inches above the upper border of the original ulceration. Ten days after, the characteristic necrosis appeared which sloughed in two weeks, and the resulting ulceration was almost completely covered by healthy skin by the last of November. None of the severe pains accompanying the development of the other necrotic foci obtained with this one.

The noteworthy features about this case were as follow: (1) The constant appearance of a subcutaneous effusion of blood in the areas which subsequently became necrotic; (2) the spontaneous development of profound erythema and structural modification in the newly formed skin exposed by the exfoliation of that which had been browned by the direct agency of the rays; (3) the cessation of pain as soon as the necrotic tissue had completely separated, a feature also exhibited by Case I; (4) the apparent failure of the direct electrical current to accelerate the separation of the necrotic tissue, and its gratifying effect upon the reparative process after this tissue had sloughed; (5) the appearance of an area of necrosis six months after the last X-ray application, in a region which had previously exhibited no evidence that such injury had been inflicted; a feature also obtained in Case I; (6) the aggravation of the pain produced by the anesthesine and talc mixture.

Although neither of these cases presents a finally completed history, what has been observed to date is sufficient to shed some additional significant light upon the influences which the X-ray experts upon the tissues, and the management of the untoward results of these influences.

First, the belief, somewhat extensively held, that a patient who "tans" well need not fear a burn, is demonstrated by these cases to be untenable. Both of these patients tanned readily and profoundly.

Second, the "tanning" and excessive epithelial proliferation of the new skin observed in Case I, and the profound erythema and structural changes of the new skin observed in Case II, all of which modifications obtained in tissues which had developed months after exposures to the rays had ceased, indicate that the physiological action of X-light is not confined to stimulant or destructive influence upon tissues that already exist, but that it is capable of modifying most profoundly and more or less permanently, the developmental functions which control cell growth. I have previously expressed a belief in this phase of influence, and that we shall ultimately find that it plays no small part in the beneficial effect exerted by the X-ray upon many cases of malignant growths.

Third, the abrupt cessation of the sharp, cutting pains simultaneously with the final separation of the necrotic tissue, would point to direct irritation by the sloughing mass, of the distal ends of nerve trunks supplying the affected parts as their exciting cause, probably through the development of toxins by retrograde tissue metamorphosis at the line of separation; a pure neuralgia in short, and which would indicate extirpation of the necrotic area by curettement or otherwise as a logical management for X-ray dermatitis of this degree.

Fourth, the accelerating influence of the direct electrical current upon the process of healing after the slough had separated, noted in both cases, is significant from a therapeutical standpoint. The power of the negative pole of the direct electrical current to hasten repair in open sores of various sorts has long been known to electrotherapeutists, but the X-ray ulceration has exhibited a peculiarly intense resistance to all ordinary measures available for this purpose, and the knowledge that we have in this modality an effective curative agent even in this condition constitutes a comfortable thought. It is probable that skin-grafting will be avoidable in many cases where galvanism is available.

Fifth, the appearance of new areas of necrosis, in Case I five months, and in Case II six months, after the last X-ray exposure had been made, admits of three hypotheses in the way of explanation. It might have been due to a cumulative characteristic of the ray, whereby the direct effect of the exposure did not fully develop until after

these lapses of time; it may have been due to a modifying influence exerted by the ray upon the developmental functions of the cells involved, whereby the younger generations of cells were unable to acquire the degree of vitality necessary for the maintenance of tissue integrity; or it may have been the indirect result of circulatory insufficiency caused by an X-ray endarteritis obliterans which had required this length of time for its full development. None of these are entirely satisfactory, however, and we shall have to await the acquisition of a fuller knowledge of the modus operandi of X-ray effects, before we can decisively account for this, and many other of its vagaries.

Sixth, the sedative effect of anesthesine upon the pain in Case I, and its aggravating influence in Case II, illustrates the statement frequently made and the truth of which is now pretty generally admitted, that no two cases of X-ray pain can be depended upon to react uniformly to the same palliative agents. In no other condition does there obtain so emphatic an exemplification of the old adage that "What's one man's meat is another man's poison." Each case must be treated according to its own individual peculiarities, and usually the only way to ascertain the peculiarities is to begin at one end of the list of therapeutical agencies and apply them successively until we find one that is effective.

Seventh, the sudden and constant appearance of subcutaneous hemorrhage preceding the development of necrosis noted in Case II, is worthy of record, but I do not at present comprehend its significance, nor can I offer a satisfactory explanation.

In conclusion, the histories to date of these two cases, constitute a warning against exposing a patient to the X-rays with even a moderate degree of frequency through long periods of time, no matter how well they seem to bear them at first. There are few conditions so pregnant with torture for the victim as a deep X-ray dermatitis, and the risk of precipitating such a disaster is only justifiable in cases presenting an absolutely hopeless prognosis under other methods of treatment.

THE VALUE OF VAGINAL CÆSAREAN SECTION: WITH REPORT OF TWO CASES.*

BY M. STAMM, M.D.,
OF FREMONT, OHIO.

To Dührssen of Berlin the credit is due for having introduced this valuable method into practise. No matter what others may have done before him he has laid down the rules and indications for the operation and given them the widest circulation. It was only through his writings, about four years ago, that I became acquainted with them and was struck by the efficiency of his method in a case of uterine cancer at four months' pregnancy. I could at that time comprehend that it was destined to take the place of ventral Cæsarean section in nearly every case where the soft parts formed the obstacle to delivery or where a narrow pelvis could be excluded. The clinical reports of operations undertaken upon various indications seem to speak favorably of this method.

Dührssen first advised the operation in the *Allgemeine deutsche Aerztezeitung*, April 1, 1895, Nos. 7 and 8, where he spoke of the treatment of eclampsia. He said that in convulsions during pregnancy it was important to empty the uterus as quick as possible and this could be done by competent hands through an incision of the anterior wall of the cervix and lower segment of the uterus. Again at a meeting of the Obstetrical Society of Berlin, January 10, 1896, he said, "The vaginal Cæsarean section, according to my view, can only be done at a clinic and with trained assistance and it is indicated where a closed and undilatable cervix endangers the life of the mother and, in rare cases, that of the child." He then gave a description of his method of operating, which he had followed in a case April 24, 1896, at the normal end of pregnancy on a patient upon whom vaginofixation was performed some years before. The large size and transverse position of the child caused him some fear of serious trouble. In this case he made a longitudinal incision through the anterior and posterior uterine wall up to the internal os and drained the uterus by a tampon. On May 29, 1896, he presented the mother and child before the German Surgical Society and gave the following indications for vaginal Cæsarean section:

1. Abnormal conditions of the cervix and lower segment of the uterus (carcinoma, myoma, rigidity, stenosis of the cervix and partial pouch-like distention of the lower uterine portion).

2. Dangerous conditions of the mother, which may be removed or relieved by prompt emptying of the uterus—affections of the heart, lungs and kidneys.

3. Conditions of the mother where death is imminent and can be foreseen. The last two indications have only value in cases where the cervix is closed and not dilatable or where the depressing influence of labor pain should be obviated as in affections of the heart and lungs. In pregnancy complicated with cancer of the uterus he advocated immediate vaginal section with subsequent extirpation of the uterus, no matter at what time of pregnancy or at what stage of labor this condition is encountered. His mode of procedure consists in curetting and cauterizing the carcinomatous tissue with thermocautery, then he ligates the basis of the parametrium on each side, the vagina is then separated from the uterine portion on all sides and, if necessary, the opening can be enlarged by an anterior longitudinal incision. The uterus is pulled down with tenaculum forceps and a rapid median incision is made in the anterior and posterior wall of the uterus sufficiently large to extract the child. After the placenta has been removed the uterus is

* Read at the meeting of the Association of American Obstetricians and Gynecologists, Sept. 23, 1903, at Chicago.

split further up and the anterior and posterior cul-de-sac opened so that the uterus can be grasped higher up with forceps and pulled down to tie or clamp the ligaments from above. The suturing of the peritoneum ends the operation.

His second case was a moribund woman suffering from mitral insufficiency and dilatation of both ventricles with a high degree of compensatory disturbance, very feeble pulse, orthopnea, cyanosis and extensive edema. The child was slightly asphyxiated, the operation lasted only about twenty minutes, but the condition of the patient was such that she could not endure the operation.

His third case, one of eclampsia, was reported in the *Centralblatt für Gynäkologie*, No. 2, 1901, p. 54. Patient was in her sixth month of pregnancy, she died about twenty-three days after operation with symptoms of pulmonary tuberculosis and pneumonia, with a return of edema and albuminous urine. As the pelvic organs had recovered their normal condition he is justified in mentioning this case in his statistics as cured. He expressed the hope that he may see the time when the classical Cæsarean section will be replaced by the vaginal section in grave cases of eclampsia and advocates the latter method where the soft parts form a serious obstacle to labor and the life of the mother or child is in danger, provided the cervix is closed or undilatable. In his monograph: "Der vaginale Kaiserschnitt," 1896, he had already specified the indications for this operation plainly and comprehensively and thought that besides cancer of the uterus and eclampsia, uremia and premature detachment of the placenta with internal hemorrhage might call for it when the cervix is closed and there is absence of pain. Retroflexion, pouch-like distention or kinking of the gravid uterus might also furnish an indication. He also claims that with such an operation, under deep anesthesia, 93.75 per cent are saved in eclampsia, on the other hand 78.9 per cent. if left to spontaneous delivery.

Simon, of Nürnberg (*Münch. med. Wochenschrift*, No. 21, 1903), reports three cases of vaginal Cæsarean section. One case was operated on two years before for prolapse of the vagina and uterus where anterior and posterior colporrhaphy with amputation of the cervix was made. The resulting condition, stenosis of the uterus and vagina, complicated the act of confinement very much. Although the pains began three days before and the water had broken at that time very little progress was made. The cicatricial stenosis of the os and vagina proved too great an obstacle for spontaneous delivery. After having made an incision through the perineum and posterior vaginal wall he made a saggital incision in the anterior vaginal wall to the os uteri. As the cervix had been amputated before there was some difficulty in hooking down the uterus. Close to the cicatricial border he separated the vagina from the uterus by a transverse incision and after having pushed the bladder up from the uterus he made a median incision of 10 c.m. into the uterine wall which enabled him to grasp the head of the child with forceps and promptly deliver a living child weighing eight pounds. The placenta followed soon, he then stitched the uterus up with eight deep silk sutures, the vagina with catgut and the perineum with silk sutures. Patient recovered fully and had no return of the prolapse.

The second case, a primipara, thirty years old, had labor pains for five days, water broke at the start. The os opened the first two days to admit two fingers and remained in that condition, though the pains continued. They gradually became spasmodic, fever set in and patient became exhausted. The doctor found the head in the pelvis pushing the cervix before it, but the latter would only admit two fingers. He was unable to assign any cause for such a condition, unless it was the rigidity which is at times met in older primiparæ. As there were signs of a living child he concluded to make a vaginal Cæsarean section. The pelvis was normal, tetanic contractions of the uterus, pulse very rapid and general condition feeble and exhausted. The child was extracted with forceps after having made an incision into the perineum and anterior portion of the cervix and uterus. The mother died three days later, but the child is living.

The third case, a primipara, twenty-four years old, at the end of pregnancy, had eight convulsions without any sign of pain and was in a comatose condition. He made dilatation with metreurynter, which caused slight pains, but increased convulsions; two hours later he made vaginal section. The cord was prolapsed and pulseless, perforation of the head in this instance was considered the simpler way. Convulsions ceased, but coma lasted two days. Recovery of mother. As I have mentioned before, Dührssen said that premature detachment of the placenta might also furnish an indication for vaginal Cæsarean section. This soon found its practical application in a case reported by Rühl (*Centralblatt für Gynäkologie*, No. 47, 1901). Patient received a slight trauma to her abdomen the day previous. The following forenoon she had a few slight pains, followed suddenly by a very severe one, as if something had ruptured inside, a moderate amount of blood was found in the vagina. Patient became unconscious and fell to the floor. One hour later Dr. Rühl found the fundus uteri near the right border of the ribs; configuration of the womb was apparently normal, the right side of the corpus uteri, however, was more prominent. The fetal parts could not be felt distinctly, there were no movements and the heart beats were also extinguished. The vagina was filled with blood clots, the cervix not obliterated, its walls were thickened and hard, the index finger could hardly be introduced, the membranes were intact and became tense during the pains, the placenta could not be felt near the os uteri. Patient regained consciousness and stated that

her pains became harder. There was a constant trickling of blood and especially so during labor pains. Rühl introduced a colpeurynter to dilate the os, but about fifteen minutes later patient became unconscious again and deathly pale, the corpus and fundus uteri formed a projecting tumor of the size of a man's head, with a distinct elongated swelling pointing toward the cervix. This led the doctor to the conclusion that there was internal hemorrhage calling for immediate operation. Patient received saline infusions and the anterior and posterior walls of the cervix were incised, which caused no great hemorrhage. The time from the incision to the extraction of the child occupied six minutes. The placenta and large blood clots followed spontaneously; hemorrhage ceased immediately after the uterus was emptied. Patient was in a precarious condition for about twenty hours, repeated saline infusions and injections of camphorated oil produced a change for the better. Rühl thinks that the classical Cæsarean section might present less technical difficulty in the hands of a surgeon not skilled in vaginal operations.

Another interesting case was recently reported by Rühl (*Centralblatt für Gynäkologie,* No. 34, 1903), under the heading "Hysterotomia anterior vaginalis owing to intense rigidity of the cervix, complicated by a tear in the lower uterine segment and parametrium. Patient, twenty-five years old, primipara, had been in labor five days before he saw her. She was extremely feeble, pulse 120 per minute, temperature, 37.8° C. She had constant pains, uterine walls were very tense and sensitive on touch, contraction ring distinct about three fingers width below the umbilicus. External genitals were not more developed than those of a girl, twelve to thirteen years old and exhibited no sign of pregnancy such as swelling, softening or discoloration. Pelvis, somewhat narrow, was funnel shaped, vagina would admit two fingers. Head was down in the pelvis pushing the lower uterine segment before it. Cervix could hardly be reached, it was high up and far back in the pelvis, hard and not dilated at all, the external os was completely closed. The water had broken five days ago and there were tetanic contractions of the uterus. As there was danger of rupture of the uterus he thought immediate delivery was indicated. There was some difficulty in bringing down the cervix and an effort to dilate it with instruments succeeded only so far as to admit one finger. He, therefore, made an anterior incision and delivered a living child by forceps. In spite of all care and multiple incisions into the vagina he tore the latter in two places and had also a perineal tear into the rectum. The hemorrhage was so severe that patient collapsed in one-half minute and, though the placenta was immediately removed and the uterus had contracted, the bleeding still kept up. The cause of the latter was found in a tear which started from the highest point of the anterior incision in a transverse direction to the left side and lower part of the parametrium. These parts were immediately grasped by forceps and, after a squirting artery was ligated, they were united by sutures which checked the hemorrhage completely. The anterior incision and vaginal and perineal tears were also united and patient made a nice recovery.

Bumm was also able to report in *Centralblatt für Gynäkologie,* No. 52, 1902, 13 cases of his own with one death of the mother due to coma in eclampsia. The indications for his operations were cancer of the uterus in two cases, eclampsia in five cases at the seventh, eighth and ninth months of pregnancy. One case of nephritis at the ninth month, another case of nephritis complicated with mitral stenosis and insufficiency was operated on in her sixth month of pregnancy under local anesthesia and greatly improved after this. One case of severe chorea, operated on in her fifth month, was delivered of twins and relieved of her chorea in about one week. One case was operated on for hemorrhage in her sixth month of pregnancy, which was due to vicious insertion of the placenta. In two cases of flat, rachitic pelvis artificial induction of labor was resorted to. Braun-Fernwald (*Wiener med. Wochenschrift,* No. 28, 1898) made the operation on account of stenosis of the cervix and vagina, he made anterior and posterior incisions. Ehrendörfer reports a case (*Centralblatt für Gynäkologie,* No. 16, 1903) where hyperemesis gravidarum formed the indication for operation at six months' pregnancy. The vomiting and salivation gradually ceased after one and a half days and she made a nice recovery. Spinelli operated on a case in 1898 for cicatricial stenosis and hydramnios with uncontrollable vomiting.

Dührssen reports another case of eclampsia (*Centralblatt für Gynäkologie.* No. 16, 1903). The patient was a primipara, her legs and face began to swell about the end of January. On February 23 her vision became disturbed, she had severe headache and vomited twice a day. On February 26, she had five convulsions, the vagina would only admit two fingers, was rigid and dark blue, cervix not obliterated and would only admit one finger. An incision in the right vaginoperineal region gave sufficient access to his fist. After he had made an anterior incision into the womb he found it necessary to make one also in the posterior portion to admit his hand. After version was made a living child was delivered. Half an hour later the placenta was removed by pressure and as there was some hemorrhage due to uterine atony a gauze tampon was introduced. The posterior incision required four and the anterior five catgut sutures. The vaginal incision was stitched up with continued catgut sutures after having left a small gauze strip for drainage. The urine was free from albumin on March 1, and patient left the hospital in good condition on March 6, 1903.

To the above reported cases I can add one of my own, where I performed vaginal Cæsarean

section for eclampsia. Mrs. J. B., Bellevue, O., about thirty-five years old, had four children. On April 22, 1903, at her seventh month pregnancy, she began to have convulsions at 8 P.M. and had about seven attacks before I saw her the next morning at 9 o'clock with Drs. Richards and Harding. She was comatose since midnight, temperature 101° F., pulse 95, she vomited several times, bowels moved three times. The cervix, not obliterated, admitted the little finger, but an attempt at further dilatation with instrument proved futile or, at least, would have been too slow. Two fatal cases in my practice gave me the conviction that more rapid delivery might have given better results. While we were preparing for the operation, at the home of the patient, she had another convulsion. The posterior portion presented more favorably than the anterior and, owing to the surroundings and scant assistance, I thought I would follow the way which seemed the easiest for me under the circumstances. On that ground I made my deepest incision into the posterior portion (about 4½ inches long) and then a more shallow one into the anterior with the knife. Hemorrhage was not profuse, as I at once introduced my hand into the uterus and made version. There was a little delay in getting the head of the child through the vaginal outlet, but the whole procedure occupied only six minutes, the placenta was removed a few minutes later by pressure and an iodoform gauze tampon introduced into the uterine cavity. The incisions were stitched up with catgut sutures and the whole operation was done in about twenty-five minutes. Patient rallied after several hours, the child lived about one and a half hours. I saw patient about two months later, she was in perfect health, a small portion of the posterior incision had not united, urine was free from albumin.

There was over 60 cases of vaginal Cæsarean section reported so far, the majority of them were undertaken for cancer of the uterus, but the number performed for puerperal convulsions is also increasing rapidly and it seems that this trouble will furnish the chief indication for such an operation in the future. Most authorities seem to agree that rapid delivery is the most important measure to reduce the mortality in eclampsia, I also think that rapid dilatation with Bossi's dilator or similar instruments will be superseded in some measure by an operation where the extent of incision or laceration is more under your control and where the wound gives more promise of healing by primary union. The operative technic consists in exposing the uterine portion by a large speculum or retractors and grasping it by two pairs of forceps on either side of the os. A longitudinal incision of 5 to 7 c.m. is then made in the anterior wall of the vagina down to the os uteri. The loose cellular tissue is then opened with scissors between the bladder and cervix. The bladder is pushed back with a small piece of gauze as far as the internal os and corresponding to that height a saggital incision through the anterior wall of the cervix is added. The upper margins of the wound are again grasped by forceps in a manner similar to morcellement and vaginal myomotomy. This exposes a further portion of the womb, the bladder is pushed up more and another incision is made through the lower segment of the uterus. If this maneuver is repeated a few times an incision of 8 to 12 c.m. can readily be made under the guidance of the eye and without opening the peritoneum. This incision is generally large enough to admit the hand and to extract a mature child. Should it, however, not be sufficient a similar procedure can be followed at the posterior portion. In the majority of cases it is probably best to wait for the natural expulsion of the placenta or, if it does not follow soon some pressure upon the uterus can be used. This operation is no doubt best done at a hospital, but it can, in case of necessity, also be done at the patient's home, as my case proves. As a rule the incision in the anterior portion is preferable, I could, however, see no especial difference in my case and would in the future be guided by circumstances. These incisions can be closed by catgut sutures or other material. Dührssen recommends uterine tamponade, others again reject it.

Since the writing of this paper, I had the opportunity of operating on a second case of puerperal eclampsia. Mrs. F. S., age twenty-five years, primipara, pregnant eight months, complained of headache for a few days. On September 6 at 4 P.M. she began to have convulsions and had about five before I saw her with Dr. Stierwalt four hours later. The doctor had given her one and a half grain of morphine a short time before. She was in a deep stupor, but could be aroused for a few moments. The head was down in the pelvis pushing before it the anterior portion of the womb, cervix partially obliterated, would admit two fingers. She had no pains; temperature 98.4° F., pulse 114, urine thick with albumin; it was like a boiled egg. As I did not wish to operate by lamplight, if it possibly could be postponed, we concluded to wait till daylight and to give her morphine or chloral in case of necessity. She was brought to the hospital early the next morning and had in all about eight convulsions, was cyanotic, tongue bleeding, dark and covered with crusts, some puffiness about the eyelids. Cervix in the same condition and there were no signs of pains. Operation began about 7 o'clock, anterior incision was made about three inches long, bladder was pushed up further, but as tissues seemed so brittle I thought it best to make also a posterior incision about 4½ inches long, this admitted my hand so that version could be made readily, child was delivered in about seven minutes; it took a few gasps but did not revive. Hemorrhage was not severe, placenta was removed five minutes later by pressure; operation lasted a little over one-half hour. Four catgut sutures united the anterior incision and

six the posterior. There was a shallow tear of the perineum which extended also through the wall of the vagina nearly up to the parametrium, this was united by continued catgut suture. Salt solution and camphorated oil were injected, pulse 110, temperature normal. Consciousness returned somewhat about 6 o'clock P.M. on the day of operation. Esbach's albuminometer showed about 10 grams of albumin (2 per cent.) after an equal quantity of water had been added to the urine, the next day it went down to one-half gram. Patient left the hospital in about three weeks in very good condition and urine was free from albumin.

MEDICAL PROGRESS.

MEDICINE.

Cyclical Albuminuria.—This is a term used by Pavy, to designate certain cases of albuminuria occurring without demonstrable organic disease of the kidneys in individuals otherwise in normal health. A. R. Elliott (Med. Rec., Dec. 12, 1903) has recently followed two cases for some time, which now present conditions which answer all the requirements demanded of this type of case—namely, periodical appearance of albumin in the urine without casts and without any other signs in the body that organic changes have occurred in the kidneys. In both these instances there was an entire absence of albumin in the morning urine, its presence occurring during the middle of the forenoon, reaching its height about three o'clock and then disappearing in the evening. Its presence seemed to depend more upon the standing posture than upon exercise or the diet. In both of these instances, however, there had been unmistakable attacks of mild nephritis in previous years from which the patients had seemingly entirely recovered, with the exception of this periodical discharge of albumin. No doubt, there had been, however, some slight organic changes, which were sufficient to influence the function of the kidneys in this way. The author believes that if these instances of functional albuminuria could be carefully traced back it would be found that in nearly every case some organic change had previously occurred. He would, therefore, suggest that they are, after all, organic in their causation, but that they may never be of sufficient importance to influence the general health.

Spontaneous Cure of Carcinoma.—While disappearance of benign tumors is undoubtedly possible, most authorities are skeptical concerning the spontaneous cure of cancer, though it is generally admitted that theoretically the cancer cells may be so interfered with in their nutrition that they degenerate. Most reported cases, according to H. Mohr (Therap. Monatshft., Nov. and Dec., 1903), were not carcinomatous at all, in others merely a period of latency set in owing perhaps to the removal of the inciting cause, such as an irritating tooth. The surrounding inflammatory reaction will gradually disappear and it actually seems as if the tumor were getting smaller. Yet, in every malignant tumor the body does not permit an unlimited growth of the pathological tissue; on the contrary, it tries to overcome the invasion by connective tissue proliferation and perhaps also by the production of specific cytolysins, and we will never be able to tell how often cancer is checked in its incipiency. Various constitutional derangements exercise an inhibitory influence, then a cessation of growth is often noted with reduced vitality and debilitating infectious diseases such as sepsis and syphilis. Concerning the influence of other diseases, very little is known, but mild diabetes seems to check and florid diabetes to hasten the growth of cancer. There seems to be a very peculiar relation between the genital organs of women and malignant growths, especially of the breast, and parturition, lactation and the menopause seem to occasionally exert a favorable influence. Beatson's operation is based upon this observation and no doubt does good sometimes. From time to time undoubted cases of pyloric cancer are reported cured after simple gastro-enterostomy; the only possible explanation here is that the removal of all irritating agencies prevented further development. Complete disintegration through necrosis and gangrene is also possible, and erysipelas, while it lacks any specific action, is able to set up so strong a reaction that the leucocytes eventually destroy the tumor cells. In intestinal growths complete ulceration has been observed through the action of intestinal bacteria, though all malignant cells are rarely destroyed. The great drawback against applying this principle in therapy is the danger of general infection. A most promising subject is that of specific cell-poisons, and it may yet be possible to destroy cancer cells by some toxin which does not influence the normal cells of the body.

Postural Albuminuria.—Probably under no conditions can albuminuria ever be physiological. Sir William H. Broadbent (Brit. Med. Jour., Jan. 2, 1904) states that a greater precision in the definition of what we mean by functional albuminuria is necessary. Although this may be admissible in the sense given to it by Dr. Pavy as a contradistinction to structural, it is vague. The albuminuria of the apparently healthy is still more unsatisfactory in designation. It may be said definitely that there is an effection which may be called postural albuminuria. This applies to that small class of cases from which have been eliminated early nephritis and nephritis in process of recovery; early stages of granular kidney; unsuspected heart disease, albuminuria from fever, from overfeeding or indigestion, gout or oxaluria. There is left a group of cases in which the characteristic feature is albuminuria on rising from bed in the morning, usually passing off in the course of the day. This condition is frequently seen in young students, and the designation of albuminuria of adolescence is appropriate, but the term postural albuminuria is better. The albumin is not due to food. It does not appear if the patient remains in bed to breakfast or after meals during the day. It cannot be toxemic; it disappears quickly on lying down. It is obviously in relation with the erect posture and scarcely less obviously with imperfect cardiovascular adjustment to the changed hydrostatic conditions. The amount of albumin is usually small. It is important that the form of albuminuria should be recognized, since the treatment required is the diametric reverse of the liquid diet and rest of ordinary nephritis. A neurotic family history is a common antecedent. The pulse often changes markedly on standing up or lying down. A high tension pulse contraindicates the probability of an existing albuminuria being postural. Another sign is that the second sound is reduplicated when the patient lies down. The prognosis is favorable, cure resulting in almost every case from improved hygienic surroundings. If, however, these cases are put on milk diet, are protected from cold and forbidden to take exercise, they may be converted into helpless and chronic invalids.

Fetal Heart Murmurs in Gravida.—Up to 1897 but three cases of this variety were on record, two of which

were reported by Hochsinger and the third by Christopher, of Chicago. J. N. Hall reported another at that time. During the first week of November a pregnant woman was admitted into the Woman's Hospital in Denver, Colo., and it was during the examination of the heart sounds of the fetus by H. G. Wetherill (Am. Jour. of Obstet., Jan., 1904), that a murmur was detected, and it was clearly pronounced and made out to be systolic in origin. It was heard two inches below and to the right of the umbilicus of the mother, and was audible over an area of about three inches of the abdominal wall. By external palpation the position of the fetus was found to be L.O.A., and the head lying rather low in the pelvis. The mother was twenty-eight years old, a IV-para and until Oct. 1 had been as well as in her previous pregnancies. The diagnosis of the presence of the systolic murmur was confirmed by examination of the heart of the child when it was born, a month afterward. The murmur was still present when the mother and child left the hospital on November 19.

Rare Form of Persistent Ductus Botalli.—Four forms of persistent communication between the aorta and pulmonary artery are recognized by O. Wagener (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 1 and 2): (1) Extreme shortness of the canal, so that there is merely a deficiency in the walls of both vessels; (2) funnel-shaped structure, the wide end of the funnel corresponding to the aorta; (3) cylindrical shape of varying length; (4) aneurysmal dilatations. These may rupture during birth and cause sudden death. At an autopsy, another rare condition was found: the canal was open in its entire length except at the pulmonic end, where a delicate membrane prevented the admixture of systemic with pulmonic blood. It was impossible to say if this membrane had formed in later life, but the observation is of value, since it would explain certain cases where the symptoms of open duct disappear as the patient gets older. The cure need not, however, be permanent, as the membrane is so delicate that it may readily rupture. A narrow communication frequently gives no symptoms, which accounts for the fact that the condition is so rarely diagnosed during life.

Vocal Cords in Double Recurrent Paralysis.—It is a well-known fact that in double recurrent paralysis, a forced adduction of both vocal cords is often noticed with every inspiration which closely presses the cords together. F. Sinnhuber (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 1 and 2) ascribes this phenomenon as observed experimentally to a rarefaction of air beneath the glottis and to the action of the muscle of the neck and pharynx which are brought into play as soon as dyspnea sets in. The adduction disappears after tracheotomy, but persists when the neck muscles are severed. Clinically, however, the rarefaction plays a less important part, since tracheotomy does not overcome the median position of the cords. It is here probably due to the cricathyroid, after fixation of the arytenoid cartilage by means of the lateral cricoarytenoid. The expiratory dilatation would then be due to relaxation of the cricothyroid.

THERAPEUTICS.

Action of Digitalis Upon the Heart.—Most of what is known concerning the direct action of digitalis leaves upon the heart, is based upon observations on the excised organ of the frog, for it has hitherto been impossible to keep the more delicate mammalian heart at so even a temperature and to introduce the circulating fluid with so uniform a pressure, that extraneous influences are entirely excluded. Since digitalis most likely influences frogs differently than man in that slowing of the pulse in the latter is solely due to irritation of the vagus center, while in the former, peripheral stimulation will also lead to bradycardia. R. Gottlieb and R. Magnus (Arch. f. exp. Path. u. Pharmak., Vol. 51, No. 1) have gone over the subject anew, with improved methods. In these experiments cats were bled until respiration ceased; then enough warm normal saline infusion to correspond to the entire amount of blood was injected into the jugular vein and this also removed. The total fluid was defibrinated and diluted to 500 c.cm. To half of this, a certain amount of strophanthin in some experiments, and digitoxin in others, was added; the other half was used as control. The heart was then excised and the fluid injected directly into the coronary arteries. It is absolutely necessary to maintain a temperature which does not vary within a single tenth of a degree and to regulate accurately the rate of flow, else variation in the beat will occur even in the control experiments. Registration by means of the graphic method was accomplished by inserting a small lever into the apex of the heart and by means of a small rubber bag in the ventricles which recorded all variations of pressure on a tambour. The result of the experiments is as follows: During the first fifteen minutes, the contractions increase considerably in number. Both ventricles participate in this, and slowing of the pulse from the beginning is very exceptional. In most cases the systole is shortened in this stage, the diastole lengthened and the actual height of the contraction increased. Considerably later, the contractions diminish in frequency; finally the heart stops in systole or the beats become very irregular. The relaxation during diastole will become less and less marked and even when pulsations are no longer recorded, the spasm may increase so that the heart finally feels very hard. If the pressure of the circulating fluid be increased, a heart which is spastically contracted, may again begin to beat, an observation which had already been made on the frog's heart and which is due to an increase in intracardial pressure. Where the heart's action is irregular, digitoxin will render it regular. Further experiments were made upon the actual work the heart does when under the influence of digitalis and there was found to be a marked increase in the output of energy with every contraction, so that $2\frac{1}{2}$ to $3\frac{1}{2}$ times more work is done than normally.

Action of Alcohol and Metals Upon the Sea Urchin.—The addition of even a small amount of alcohol to sea-water containing very young fertilized eggs of the sea urchin seems to be very injurious to the development of this animal: cell-division and gastrulation are considerably delayed and the motility of the mesenchyma cells is interfered with so that the skeleton is but incompletely developed and its various branches show atypical arrangement. Older eggs are more resistant and the concentration must be increased considerably to have any effect. Concerning the toxicity of various alcohols, I. Führer (Arch. f. exp. Path. u. Pharmak., Vol. 51, No. 1) finds that prophylic alcohol is three to four times more poisonous than ethylic and this again three times more poisonous than methylic. Sugar and urethane possess the same action to a less pronounced degree. The addition of arsenic to sea-water does not influence cell-division or gastrulation, but the invagination of the intestine is delayed. Copper brings about atypical division while mercury, even in very high dilution, kills the eggs immediately.

Action of Drugs on the Coronary Circulation.—The action of the heart stands in intimate relation to its blood-supply and the condition of the coronary ar-

teries. If the blood-pressure rises with more active cardiac contraction, more blood will also pass through the heart-muscle so that the heart will be able to work against increased resistance. The width of the blood-stream within the heart also plays a prominent part in the nutrition of this organ and it is a significant fact that many poisons have an appreciable influence upon the tonus of the coronary vessels. Since it is still impossible to study the mammalian heart in connection with the nervous system, the experiments of O. LOEB (Arch. f. exp. Path. u. Pharmak., Vol. 51, No. 1) concern themselves solely with the peripheral action of drugs. The heart was isolated, blood allowed to circulate through the coronary system under constant pressure and temperature and the amount of blood escaping from the coronary veins into the auricles, carefully measured from minute to minute. In control experiments a slight contraction of the vessels was noticed, that is, the escaping blood became less each minute; this did not, however, interfere, as there never was a sudden rise or fall, such as would be expected upon the addition of an active drug to the circulating fluid. Briefly, the results are as follows: The coronary vessels are not much influenced by strophanthin, while digitoxin contracts them so strongly that only half the amount of blood is allowed to flow through after a few minutes. Caffeine and theobromine increase the frequency and volume of the pulse; the amount of blood discharged by the coronary vein remains the same or is slightly increased. The latter need not depend on dilatation but may be due to the increased heart action; it is more marked with theobromine than with caffeine. Amyl nitrite in a concentration of 0.06-0.2 per cent. does not influence cardiac contraction but leads to the formation of methemaglobin. Larger amounts dilate the vessels, still larger ones reduce the heart's action so that less blood escapes. Since the chief therapeutic action of amyl nitrite is directed toward the central nervous system, these experiments prove little. Ether dilated the vessels and interfered seriously with the heart-beat; chloroform proved so toxic an agent that accurate observations could not be made, while alcohol even in high concentration seemed to have little effect other than an increase of the pulse-volume.

Cumulative Action of Digitalis.—If cats receive a toxic dose of digitoxin, it requires some time before slowing of the pulse will appear; this slowing may, however, persist for seven days before the animal dies. Sometimes the pulse becomes extremely frequent and irregular before death; at other times, extreme bradycardia persists. The intensity of the symptoms does not depend alone upon the amount of drug circulating in the blood in a given time, but also upon the way it is given: thus a single dose may kill, while the same amount given in two doses during twenty-four hours need cause no toxic symptoms. Many small, inactive doses will cause summation of effect, so that a slowing is noticed after several days; this slowing will persist for days like after a single large dose, but toxic symptoms are generally avoided. Digitalin acts more rapidly but the bradycardia persists equally as long as with digitoxin, according to A. FRAENKEL (Arch. f. exp. Path. u. Pharmak., Vol. 51, No. 1). It is much easier, however, to determine a continuous dose without inducing toxic symptoms, but even after ninety days a slight increase in the dose will be followed by vomiting, since tolerance is not established. Strophanthin acts still more rapidly, but the same cumulative action develops. In this respect all three substances seem to be alike. For each one there is a daily dose which does not become toxic even after weeks. The fatal dose of digitoxin is about 0.08 milligram per kilogram; this corresponds to 0.48 milligram of digitalin. With the former glucoside, one-third of the fatal dose will cause intoxication after the third injection; with the latter, as much as one-half may be given for weeks with impunity. The degree of cumulative action probably does not depend on the rate of excretion, since strophanthin, being readily soluble, would be voided quickly; it is most likely due to some compound formed within the heart muscle which is only broken up with difficulty. The time which elapses before the symptoms appear, seems to depend solely on the solubility. It may be said in a general way that digitoxin is indicated where a short energetic cure is desired; digitalin and strophanthin are safer for long-continued daily use and the latter especially where rapid action is desired.

Pure Carbolic Acid in the Treatment of Smallpox.—This disease is relatively prevalent in the eastern Canadian provinces. JAMES T. NEECH and F. J. HODGSON (Lancet, Dec. 26, 1903) report their experiences by this method of treatment in 136 cases. Of this number five died, which gives a death rate of 3.6 per cent. The epidemic was a mild one. The bulk of the patients were not efficiently vaccinated, so that the character of the disease and the modifying effects of vaccination did not materially contribute to this low rate. The method adopted was to apply the pure carbolic with a small camel's hair brush to the vesicles over a certain area each day until all had been touched. These applications were continued until the vesicles showed signs of drying up. Toxic carboluria was present in but two cases, both belonging to one family, so that idiosyncrasy might have been present. In a number of cases only one side of the patient was treated with carbolic acid, the other receiving applications of camphor or guaiacol or formalin. In every case it was plain to see that the carbolic acid was the best. The pain of the applications is very slight, but to compensate for this, the itching was immediately and in most cases permanently relieved. The postules rapidly shriveled and the further development of papules and vesicules was either prevented, or, if not ahorted completely, very nearly so. All vesicles were scabbed under this treatment in from five to ten days and in from ten to eighteen days the scabs had fallen off, except those in the palms of the hand and soles of the feet. The tendency to the formation of scars was very much reduced by the treatment. The offensive odor characteristic of the disease was entirely absent. The absorption of septic material from the postules was almost entirely stopped. This kept the temperature at a relatively low level after the appearance of the pustular stage, it never rising above 102° F., even in confluent attacks in the unvaccinated. Delirium was infrequent and no rise of pulse marked the advent of the pustular stage. The danger of infection by aerial convection is so much lessened that patients can with safety be discharged ten days before the usual time. Under this treatment, in these 136 cases, there was an entire absence of complications.

Arsenic Habit.—Some interesting experiments are recorded by W. HAUSMANN (Deut. med. Woch., Dec. 31, 1903), who was able to immunize fowls and dogs against arsenic by treating them with repeated small doses. The degree of immunity was very slight and resembled that which is seen among the inhabitants of Steiermark in Europe who are renowed as habitual arsenic eaters. These people and also the experimental animals are known to succumb when larger doses are given and the amount tolerated is even less than that ingested by normal individuals who had never been accustomed to the drug. It was found that the arsenic was less toxic in the powder form than in solution.

SATURDAY, FEBRUARY 20, 1904.

ARE EXCITATION, INHIBITION AND NARCOSIS DIFFERENT PHASES OF THE SAME ACTIVITY?

There are no three processes in the physiology of the nervous system that to so great a degree challenge the speculative powers of physiologist and neurologist alike, as excitation, inhibition and narcosis.

The latest theory of the nature of these mysterious phenomena is advanced by one who has worked and pondered over them for many years, by N. E. Wedensky (*Pflüger's Archiv*, Nov. 19, 1903), who holds them all manifestations of one common activity.

Hitherto physiologists have attributed excitatory and inhibitory manifestations to distinct centers and nerves, whose functions are diametrically opposed to each other, the former giving rise to oxidative or catabolic, and the latter causing synthetic or anabolic processes in the tissues affected. The fact that stimulation of cortical motor areas, as discovered by the author and confirmed by Hering and Sherrington, produces not only contraction of certain muscles but also relaxation of the antagonists of the latter, can have only one explanation, namely, that inhibitory phenomena in the nervous system are universal and are evoked simultaneously with every excitatory process. The author questions whether it is necessary to assume the existence of special inhibitory mechanisms, and suggests that the apparatus which usually stimulates, may at times exert instead the opposite effect; that along one and the same path and to one and the same endorgan, under certain conditions, either excitatory or inhibitory impulses may pass.

The inhibitory action of the vagus was at first attributed to an exhaustion of the nerve produced by strong shocks, yet it has been shown in the case of muscle-nerve preparations that as soon as the inhibitory influence has gone, it is possible to get the muscle to react to weak excitatory stimuli. Closely allied to this is the subject of narcosis, which has been attributed to the power of the nerve-cell to draw in its dendrites, which power would cause the phenomena of sleep and narcosis by breaking the intimacy of contact between contiguous nerve-cells. There is no connection between nerve excitability and nerve conductivity. The former may be suppressed while the latter will survive. Thus chloroform, ether, carbon dioxide and alcohol would narcotize the nerve, reducing its excitability, and yet not affect in the least its conductivity to nerve-impulses. Wedensky found that in the early stage of the narcosis of a part of a nerve there is really a reduction in the conductivity for all degrees of impulses excited in the normal part of the nerve (provisional stage), but in the later stage of narcosis the more powerful impulses are not transmitted by the narcotized nerve, while weak impulses are freely transmitted (paradoxical stage). The narcotized stretch of nerve preserves its power of conducting weak impulses longer than any other portion.

The explanation of these phenomena is that there is no distinction, as processes, between conductivity and excitation. In the paradoxical stage the impulse starting in the normal portion of the nerve produces in the narcotized portion an inhibitory effect. This has been proved by the experiment of stimulating the narcotized portion in such a way as to produce a weak contraction and before this has disappeared, to send into the nerve above the narcotized portion another shock, with the result that the contraction suddenly ceases: as soon as the latter shock is discontinued, the contraction is resumed. This experiment is of engrossing interest for three reasons: First, it shows the inhibitory influence of one portion of the nerve upon another. Second, while formerly the narcotized por-

tion was considered as offering a resistance to the oncoming impulse, the above experiment teaches that the oncoming impulse, by acting on the narcotized portion which it is obliged to traverse, causes the blocking of its own passage. Thirdly, there is a reciprocal effect, that of the narcotized portion on the oncoming impulse and that of the impulse on the narcotized portion. The experiment leads logically to the conclusion that excitation, inhibition and narcosis border upon and merge into one another. In the later phases of the narcosis of a part of a nerve, tetanic stimuli applied to the normal portion produce a relatively long after-effect of inhibition, leaving the nerve in a condition of deeper narcosis.

What, then, is narcosis? If this is in direct relationship with inhibition or, as seen above, merges into it, while the latter is firmly bound up with the process of excitation and in certain cases is a modification of it, corresponding to strong excitatory impulses, while weak ones produce the customary stimulating effects, then narcosis would be nothing more than a mere modification of excitation. By using ordinary chemical stimuli, the author could produce conditions in the nerve similar to narcosis. The same could be brought about by high temperatures, but not high enough to kill the nerve. The reduction in conductivity brought about by passing a constant current through the nerve, produces in its early stages the same paradoxical condition noted in the early stages of narcosis. In fact, many forms of stimulation, chemical, mechanical, electrical and thermal, of a certain strength and duration, evoke in the nerve the same condition as narcotics. This condition the author terms "parabiosis," which has a more generalized significance than the word "narcosis," inasmuch as it represents the general reaction of the nerve to heterogeneous influences and is also the condition through which all nerves pass antecedent to death. It also represents a condition which is much more general than that of excitation or activity in the restricted sense. The nerve is capable of passing through four conditions, which merge imperceptibly into one another, and which, in order, are: A, Rest, B, Activity, C, Parabiosis (Narcosis, Inhibition), D, Death. B and C represent the condition of excitation. B is that form and stage of excitation which reveal themselves by means of outward effects. C is a condition of stable excitation remaining localized at its place of initiation. The transition from A to B may be regarded as increased irritability. But if the agent employed has not the property of producing an excitation in the ordinary sense, the increased irritability may pass directly into C, as occurs with chemical stimuli in weak solution and the majority of poisons. In individual instances the direct transition from A to C is possible without the intermediate phase of increased irritability (the action of ammonia). The transition from B to C is shown by all those stages termed by the author "transitional," namely, the provisional, paradoxical and inhibitory stages. Finally, under certain conditions C passes into D, inhibition in narcosis merges into death. It is well known that stimulants and narcotics in greater intensity and on prolonged action usher in final dissolution. Wedensky believes that every agent, before it kills the nerve, causes it to pass through the condition of parabiosis, just as the dying muscle first passes through the condition of rigor mortis.

OPERATIONS FOR NEPHRITIS.

In the symposium on nephritis at the recent meeting of the Medical Society of the State of New York, published in abstract in the Medical News, February 6, 1904, a number of very interesting considerations with regard to the possible extension of operative procedures to the cure of nephritis were brought up.

There seems no reason to doubt now that surgery can do something for kidney disease, though it cannot accomplish as much as has been fondly hoped at times in quite recent years. Mr. Reginald Harrison's operation for the relief of hyperemic congestion of the kidneys has proved to be of service in other hands besides his own. As the result of his observations when nephritis occurs in the course of an infectious disease and symptoms of renal inadequacy begin to assert themselves, it would seem advisable for the medical man to be ready to call a surgeon in consultation. If in a case where there have been casts and albumin for some days the urine begins to grow markedly less and finally is passed in small quantities, or even absolute anuria occurs for twelve to twenty-four hours, then a hope for the patient may be found in the splitting of the fibrous capsule of the kidney.

Mr. Reginald Harrison has very picturesquely called this condition, "glaucoma of the kidney." When the kidney is laid bare the fibrous capsule is found very tense and as soon as an opening is made in it, along the white line of the external edge the parenchyma of the kidney comes bulging

out of the capsule. Within a few hours after the operation as a rule, the kidneys begin to secrete again and usually a lessening of the toxemia seems to occur.

With regard to the so-called Edebohls operation, and the removal of the fibrous capsule of the kidney with the idea of providing a new circulation for the cortex of the kidney some very interesting additions to our knowledge were made. Dr. Willis G. Macdonald, of Albany, called attention to the fact that every surgeon who has operated much on floating kidney has found not infrequently that the fixation of a movable kidney in the loin was followed by a very notable improvement in urinary symptoms. Whenever a kidney is very movable there is almost sure to be some albumin and casts in the urine. The albumin is usually not much in amount. The specific gravity of the urine is about normal. The casts are not of the dangerous degenerative varieties, they do not contain broken down cellular material nor blood cells, but are simple hyaline cylinders. After the operation these urinary symptoms practically disappear and the patient may live for many years without any further symptoms of nephritis. The condition seems to be almost the same as that of the kidney of pregnancy, which, during actual child-bearing, may give all the symptoms of a real nephritis and yet clear up completely after labor, leaving no trace of the supposed serious condition that existed.

From this, however, to the cure of real nephritis, by stripping the kidney capsule in order to secure a new blood supply by the adhesions which form is a long step. As Dr. Van Cott, of Brooklyn, said, the hope in such a case must be that somehow the blood supply will be obtained from the fatty capsule of the kidney. Unfortunately for the theory, however, the blood vessels of the fatty capsule are not numerous and the course of the blood in them is away from the kidney. When fibrous capsule is removed in animals a new connective tissue covering for that organ develops much thicker than before and commonly sends down strands of connective tissue into the secreting substance of the cortex. Like all connective tissues, this has eventually a tendency to contract, and during the course of contraction it seriously interferes with the parenchymatous structures in its neighborhood. There seems to be very little hope on general principles of securing a new blood supply for the kidney by the mere removal of the fibrous capsule, even though it should not regenerate.

Supposing, however, that an additional blood supply should develop for the secreting portion of the kidney, it is doubtful whether this would be of any particular benefit.

Not long since a distinguished comparative anatomist was present at an operation done on a young doctor for nephritis with stripping of the capsule as the central idea for possible relief of symptoms. He had never seen the operation done before and he asked how soon they expected the new blood vessels to form. They said in a few days, though of course they expected them to continue to grow for several weeks or even more. His reply was that if they expected them to grow in ten years, he might think something of their theory.

It is a difficult matter, however, to compare theory with experience. There are certainly some cases reported, as for instance, three at the meeting of the American Physicians in Washington, last spring, in which relief was afforded by the performance of the Edebohls operation. While it may not be beneficial for many cases, there seem to be some in which it does good.

In the meantime medical men must remember that mild cases of nephritis or even those that are severe, but have already lasted for many years, should not be subjected to the strain of an operative procedure with the associated irritation of the administration of ether, until the status of the operation has been more definitely determined by its application to more hopeless cases. Every physician of any experience in kidney disease has patients under observation who have suffered from nephritis for ten or even fifteen years and yet are fairly well, only that they lack endurance. Such patients are much more likely to be harmed than helped by any operative procedure, for it is possible that they may live out a normally long life, even with damaged though not inadequate kidneys.

ECHOES AND NEWS.

NEW YORK.

Columbia and the College of Pharmacy.—Negotiations are on foot to make the College of Pharmacy a part of Columbia University, subject to the approval of the members of the college at the annual meeting on March 15. Nicholas Murray Butler, President of Columbia, has been nominated President of the college by the Trustees of that institution. Dean Charles F. Chandler, now President of the college, will become the First Vice President. Several years ago proposals by the College of Pharmacy to unite with Columbia had no result. Recently, however, it had been resolved by Columbia

that some provision must be made in its educational system for pharmacy. Michigan, Wisconsin, Northwestern and Minnesota have heretofore been the largest universities recognizing pharmacy. It is proposed that the college will hold the same relation to Columbia that Barnard and the Teachers' now do. Next month's annual meeting is the seventy-fifth anniversary of the founding of the college, in 1829. The rest of the ticket nominated includes: Second Vice President, William Jay Schieffelin; Third Vice President, Herbert D. Robbins; Trustees to 1907, John R. Caswell, Otto P. Amend, Oscar Goldman, Adolph Henning, and Charles H. White.

Examination for Superintendent of New State Hospital.—Five candidates for appointment to the post of superintendent of the new State Hospital for the Treatment of Consumptives were subjected on Feb. 13 to an actual test of their ability to deal with tuberculosis. The candidates, who are all physicians of at least six years' experience in general practice, and of one year's service in a hospital, were taken to the Albany Hospital by the Board of Examiners, where each was required to examine and discover the physical condition of five patients. The institution, which will be ready for occupancy within a short period, is located at Raybrook, in the Adirondacks.

Flower Hospital's Physical Therapy Clinic.—This hospital has recently put in a thorough equipment of electro-therapeutic and mechano-therapeutic appliances.

Bacteria and Money.—New York money may not be so dangerously dirty after all. Dr. Thomas Darlington, President of the Health Department, last week received a verbal report from Dr. Park, the bacteriologist who is developing germ cultures from old bills and copper coins, and the President was relieved to hear that if there were any malignant germs in the money they were not to be discovered under the microscope. Neither Dr. Darlington nor Dr. Park were satisfied, however, the money does not figure in the transmission of disease, and in consequence the investigation is to be carried on to a finish. Washes have been made from the cultures and they will be injected into rabbits and guinea-pigs. Indeed, that course of investigation has already been begun, and there are several of the little animals with the extract of money in their veins under observation. "It will take several weeks," said Dr. Darlington, "before the disease germs, if they exist, take effect upon the animals which are being used in the experiment. For that reason it cannot positively be said that money is not a medium for the propagation of contagious diseases. Dr. Park is carrying on a most important experiment with copper coins. It is a question, in my mind, whether copper does not exercise a fatal effect on germs of all kinds. Dr. Park has placed germ cultures on a number of these small coppers and is watching them to see if they survive."

Report of Adirondack Cottage Sanitarium.—We are pleased to acknowledge the receipt of the Nineteenth Annual Report of this institution, which is a modest little booklet given over largely to statements of cases treated, with their results, and to acknowledgment of moneys received from friends of the institution. There is no evidence of vain boasting or theatrical display, nor does the pamphlet abound in high sounding phrases telling how great a work is being done by this pioneer among consumptive sanitaria. All that is left to the reader to be gathered from actual results. In grateful recognition of the kindnesses of its supporters, the report says:

"Again, as in the past, the deficit in the yearly running expenses has been met entirely by voluntary contributions of the Sanitarium's friends, and it is a source of congratulation that the expense to the patient, $5 a week, has been kept the same for twenty years, in spite of the greatly increased cost of operating the institution due to the growth and expansion of the work in many directions, the perfection and development of methods, the many additional advantages the patients now enjoy, and the higher cost of fuel, provisions, and supplies."

During the past year 298 patients have been treated, which is the largest number since the establishment of the Sanitarium. To find out as nearly as possible the benefit derived by its patients from the course of treatment outlined and also as a matter of scientific statistical interest, Dr. Lawrason Brown, the Resident Physician, has made a very exhaustive inquiry into the records of previous cases. "Of 1,500 cases which have been discharged from two to seventeen years ago, 334 could not be traced, leaving 1,066 which have been traced. Of these, 46.7 per cent. are still living. Thirty-one per cent. are known to be well at present; in 6.5 per cent. the disease is still arrested; 4 per cent. have relapsed; 5.2 per cent. are chronic invalids, and 53.3 per cent. are dead. Thus we learn that 31 per cent. of all cases discharged from two to seventeen years ago have remained well." This is certainly very encouraging when we consider how terribly fatal the disease is considered to be, not only by the laity but by the profession as well; and it is likely if the present rate of progress continues that experience derived from the treatment of an increasing number of patients for another seventeen years will be the means of doubling this percentage.

Especially commendable is the fact that the institution is primarily for those in very moderate circumstances. The rich can always be benefited for a time at least by careful nursing, change of climate, and all the safeguards that go with wealth and luxury; but here we have a place where wealth is actually a bar to entrance, and the primary object still is, as it was conceived in the mind of its founder at the beginning, to provide for the care of the nominally poor.

Summing up the year's work the following facts are noted:

"The work done by the Sanitarium during the past year may be summed up briefly as follows: Two hundred and ninety-eight patients have been treated. To two hundred and fifty-seven of these the institution has furnished the best possible means of restoration to health at a nominal cost, and to forty-one entirely free of cost to them." The names of many of America's most widely known philanthropists occur in the record of beneficers, and not the least among these is that of the indefatigable physician to whom the whole world owes a debt of gratitude in his zeal for the stamping out of tuberculosis on this side of the Atlantic.

Bad State Charity Laws.—The annual report of the State Charities Aid Association to the State Board of Charities was made public last week. It contains, among other things, a review of the bills that came before the legislature last year affecting the State's charitable institutions. It says that the legislative session of 1903, "while less momentous to the wards of the State than that of 1902, was characterized by a considerable number of important

measures affecting the welfare of the poor in their homes and public dependents in institutions." One of the most disastrous measures passed by the legislature and signed by Gov. Odell, the report says, was that which forbids the establishment of any hospital or camp for the treatment of patients suffering from pulmonary tuberculosis in any town without the consent of the town's governing board and of the Board of Supervisors of the county in which the town is. "The effect of this law," says the report, "is to make it impossible for any city in the State, or any fraternal order, charitable society or philanthropic individual to establish a hospital, camp or other establishment for the treatment of consumptives outside the city limits, except under conditions which are practically prohibitive." The report says that in the opinion of the association the country districts were sufficiently protected by the laws then existing, which forbade the establishment of any institutions for consumptives in the State without the approval of the State Board of Health and which laid down other restrictions. The report asserts also that the disease, instead of increasing, decreases in the districts in which institutions for its treatment are located. The report adds:

"By the passage of this law the thousands of sufferers from pulmonary tuberculosis in this State may be prevented from receiving the care and treatment which would result in their cure or improvement. More than 60 per cent. of the people of this State live in cities of 40,000 inhabitants, and it is among the poor in cities that the disease is most prevalent. It is deplorable that the interests of these unfortunate people should be subordinated to local property interests which were already amply protected by previously existing laws." Speaking of Bellevue Hospital the report says: "Steadily and by no means slowly the morale of Bellevue Hospital has followed in betterment the refreshing change in the appearance of its wards and halls, with constant effort to lay the foundations for a change in the attitude of the public toward the 'Bellevue' of the sensational press—if anything but the upbuilding of the hospital can accomplish this. The board of trustees has made gratifying progress also in its endeavor to secure a new and adequate plant for this hospital."

The report emphasizes the urgent need for new State institutions for the feeble-minded, the idiotic and the epileptic, recommends that the State Board of Charities should have the power to transfer inmates from one State charitable institution to another, and to determine the capacity of each institution, and indorses all efforts that are being put forth to improve the industrial features of the State's charitable institutions.

PHILADELPHIA.

New Medico-Chirurgical Hospital Opened.—The new Medico-Chirurgical Hospital, rebuilt after the explosion of a water heater one year ago which virtually ruined the old building, is now ready for the reception of patients. It is the best that modern hospital construction and equipment can furnish. General wards, private wards, and private rooms are included in the building.

Medical Inspectors Appointed.—The forty additional assistant medical inspectors have been appointed by the Bureau of Health and been sworn into office. The districts are determined by ward lines. In several instances where the wards are small one inspector has charge of two wards; in case of the larger wards, two or even three inspectors are assigned to a ward. The inspectors will look after cases of contagious diseases, inspect schools, and do the city's vaccine work. Instruction in the shape of short lectures will be given the members of the corps until they are thoroughly conversant with their duties.

Society for Prevention of the Spread of Tuberculosis.—At a recent meeting of this society an active campaign for the prevention of the spread of tuberculosis and other contagious diseases was outlined. Among the measures proposed were the cleaning of streets only between midnight and six o'clock in the morning with thorough wetting of the streets before cleaning, withdrawal of all trolley cars with upholstered seats, heating of cars in cold weather, and the enforcement of the anti-spitting ordinances. It was decided to make an exhibit at St. Louis of charts, maps, and statistics relative to the prevalence of tuberculosis in Philadelphia.

Smallpox Statistics.—The returns of smallpox cases throughout Pennsylvania for January show a considerable decrease as compared with those of December or November. In Philadelphia there has been no lessening in the disease, and the death rate for January was nearly three times that for November. During the three months mentioned there were in the State 2,456 cases of smallpox with 297 deaths. About two-fifths of the cases and two-thirds of the deaths occurred in Philadelphia.

The Administrative Control of Tuberculosis.—Dr. Hermann M. Biggs, of New York, in an address on the above subject before the Phipps Institute February 15, gave a résumé of the work accomplished along this line by the New York Health Department. He showed in a most convincing array of statistics that the spread of the disease had been checked by the methods employed in that city and also stated that any municipality could accomplish similar results if active measures were employed. That no new discoveries are being taken advantage of in New York was made emphatic by Dr. Biggs, who said at the outset that it was remarkable that so little had been done in controlling tuberculosis when we consider that practically all we now know regarding the sanitary measures necessary were known fifteen or twenty years ago. Results come from putting into practice the things that are commonly known. Mayor Weaver, who presided at the meeting, said that Philadelphia was ready to put in practice the methods shown to be so successful in New York whenever the people, or even the medical profession, of the city were ready for their adoption.—See MEDICAL NEWS, Special Article, this week.

Changes in the Intercostal Muscles in Pneumonia and Pleurisy.—At the meeting of the Pathological Society of Philadelphia, January 28, Dr. W. M. L. Coplin read a paper on this subject, stating that no important studies of the relations, if any, existing between the intercostal muscles and inflammations of the lung and pleura had been carried out. In this preliminary note he gave the findings in seven cases that have been studied. Of these, two were croupous pneumonia, two tuberculous pleurisies, two acute pneumococcus pleurisies, and one chronic empyema. The changes observed in the muscles were as follows, though their order of occurrence may not be the same as given: (1) Granular degeneration or cloudy swelling of the muscle fibers. This is probably a part of the systemic action of toxic bodies circulating in the blood; (2) the muscle fibers are dissociated, edema is present, but there is but little

fibrin containing substance. Groups of muscle fibers and bundles show changes that cannot be differentiated from the hyaline degeneration described by Zenker as occurring in the muscles of the abdominal wall in cases of typhoid fever; (3) the preceding change is increased and fibrin and leucocytes (mainly mononuclear) become abundant. Bacteria are often conspicuous. From the specimens studied it is inferred that the necrotic material thus formed is removed and sclerosis results. In the chronic empyema newly formed and forming fibrous tissue is present and there is conspicuous fatty infiltration of the muscle. This seems to be due to the long-continued infection of the pleura. The pathogenesis of the condition described is not entirely clear but is probably explained by the lymph tracts of the muscle carrying off toxic material from the pleura. The alteration in physical sounds over the affected area, the occurrence of intercostal neuralgias during the course of pneumonia, etc., suggest themselves from the study of the muscle changes thus briefly outlined.

Honors to Dr. Wiggin.—Dr. Frederick Holme Wiggin, of New York, at the invitation of the Montgomery Gynecological Society of the Jefferson Medical College, delivered an address on "Some Practical Points in Abdominal Surgery with Special Reference to a Simple Technic for Appendicectomy and Intestinal Anastomosis," before the student body of that Institution, in the lecture room of the college, on the occasion of the Annual Meeting of the Society, which was held on the evening of Feb. 2. Later in the evening Dr. Wiggin was entertained at a dinner given by the Society at the Colonnade Hotel in his honor.

CHICAGO.

Addition to Presbyterian Hospital.—The Directors of this institution are considering plans for the construction of additions to the hospital, which will include a surgical pavilion and a new out-patient dispensary for the poor. Part of the $500,000 necessary for these additions has already been pledged.

Work of the Chicago Pasteur Institute.—The Director of this institute in Chicago reports that since the institute was opened, July 2, 1890, 2,026 patients have received the anti-hydrophobic treatment. Of these, 1,807 had been bitten by dogs, 76 by horses, 57 by cats, 19 by cows, 18 by skunks, 25 by other animals, and 22 were infected by hydrophobic human beings. Of individuals bitten by animals absolutely known to have been rabid, 982 were treated; of patients bitten by animals presumed to have been rabid because of symptoms of disease during life, 776 were treated, while 268 cases were cared for in which rabies was suspected. Only 7 deaths were reported, a mortality of 0.34 per cent. Six individuals abandoned treatment, two of whom subsequently died from hydrophobia.

Examination of the Urine and Segregated Urines as a Means of Diagnosis in Surgical Diseases of the Kidney.—Dr. M. L. Harris read a paper on this subject before a recent meeting of the Chicago Medical Society, and among other things he said that as most of the so-called surgical affections of the kidneys are due to microorganisms, it is important to know the kind of infection present. This means in most cases a bacteriological examination by the usual culture and tinctorial methods. The essential point in this connection is the obtaining of the urine uncontaminated with organisms from external sources. In the female the urine should invariably be obtained by the use of a sterile catheter introduced after proper cleansing of the parts. In the male the same procedure may be used, or if there has been no disease of the lower urinary tract, it is sufficient to urinate, after thoroughly cleansing the urethral opening and discarding the first portion that escaped into a sterile receptacle, from which inoculations should be made immediately. If there has been an infection of the urethra, this canal should be cleansed as thoroughly as possible by irrigation before attempting to collect the urine. The microorganisms most frequently found are the *Bacillus coli communis, Bacillus tuberculosis,* and various staphylococci and streptococci, the *Bacillus proteus,* and rarely the *Bacillus typhosus* and *Diplococcus pneumoniæ.* The effect of the presence of these bacteria on the reaction of the urine varies, so that the reaction of the urine becomes a point of some diagnostic significance. To be of value, however, the reaction must be taken at once, as an acid urine may become more acid or change to alkaline within a short time after it is passed, owing to external contamination. The normal acid reaction of the urine is not changed by the colon bacillus, the tubercle bacillus, or the streptococcus, while the staphylococci and the *Bacillus proteus* render the urine alkaline, owing to the decomposition of urea with the formation of ammonium carbonate. In the presence of an alkaline urine it should be determined whether the alkalinity be due to the so-called earthy bases, to alkalies introduced medicinally, or to ammonia. If due to ammonia, it indicates an infection with some urea decomposing organisms. The tubercle bacillus does not grow on the usual culture media, but is recognized by its peculiar tinctorial properties. In practically all cases of tuberculosis of the kidneys this bacillus may be detected in the urine, if a sufficient number of carefully conducted examinations be made. The possibility of confounding it with the smegma bacillus should be borne in mind and the proper precautions taken. The use of the microscope is absolutely necessary in order to detect the presence of pus or blood in the urine in anything but the most apparent macroscopic quantities. This statement would not have been deemed necessary, did not one still occasionally hear a physician speak of the cloudiness or deposit due to precipitated urates as pus, or the high-colored cloudy urine of concentration as due to blood, simply on their appearance. The presence of pus in the urine is always an indication of an infection of some portion of the urinary tract, unless it has ruptured into it accidentally in some neighboring organ. While the kind of infection should always be determined when possible by the culture methods, as already mentioned, still the following points are of practical clinical importance:

A pus-containing urine, alkaline owing to the presence of ammonia, is probably due to the presence of the staphylococcus or proteus. A culture obtained from an acid, pus-containing urine is most commonly the colon bacillus. An acid or neutral pus-containing urine which remains sterile on ordinary culture media is almost always due to tuberculosis, even though no tubercle bacilli are found on examination. Mixed infections, of course, may exist. Blood in the urine, when it comes from the kidneys, is usually due to malignant tumor, tuberculosis, or renal calculus. The essayist then considered the blood in cases of malignant tumor, tuberculosis, renal calculus, etc. The most careful ex-

amination of the urine often furnishes sufficient data upon which to base a correct diagnosis as to the location of the lesion. The history will frequently make up the deficiency, but only too often this is also wanting, when recourse must be had to other means. These are mainly cystoscopy, or inspection of the interior of the bladder, and the collection of the urine directly from each kidney separately. The use of the cystoscope is absolutely essential to a correct diagnosis in many diseases of the urinary tract. Collecting the urine directly from each kidney separately is the greatest advancement which has been made in the diagnosis of surgical renal affections in modern times. There are two practical methods of accomplishing this, namely, the use of the urine segregator and catheterization of the ureters. Each of these methods has its advantages and its limitations. After quite an extensive experience with the segregator, he stated that its intelligent use in suitable cases furnishes results which are reliable and gratifying. It does not take the place of the cystoscope, but should be used in connection with that instrument. It does not supplant entirely catheterization of the ureters, as there are cases in which the latter is the more suitable, but that it does have a very useful field is certain. The advantage of collecting the urines directly from the kidneys is very great. We are thereby not only able to exclude entirely the lower urinary tract, but to determine whether the disease affecting the kidneys is bilateral or unilateral, and if the latter, which side is involved. No diagnosis of these affections is now complete without these facts. An examination of the urine in the surgical diseases of the kidneys must take into consideration not only the pathological constituents but also the comparative amounts of normal constituents eliminated by each kidney, in order that the proper treatment may be carried out and a correct prognosis given.

Efforts to Prevent and Suppress Typhoid Fever.—Rules and regulations have been prepared by the Illinois State Board of Health with reference to the prevention and suppression of typhoid fever. They were formally adopted by the board at its annual meeting, copies of which have been sent to all the newspapers in the State, and to every county, township, village and city health officer, and they will also be distributed among the people by the local health officers.

Antitoxin and Diphtheria.—Proof that antitoxin saves hundreds of lives in Chicago each year is offered by the Health Department in its weekly bulletin. The use of antitoxin in the treatment of diphtheria was begun by the city nine years ago, and since that time the mortality has been 6,088, while during the nine years before 11,488 persons died. The decrease has been 5,400, or 47 per cent., while the population has increased nearly 600,000, or 52 per cent. Considering population, the decrease in deaths is given as 63 per cent.

GENERAL.

New Sewerage for Baltimore.—The city of Baltimore is constructing a sewer system which will cost $10,000,000. The discharge of all sewage into Chesapeake Bay is to be actively prohibited.

An Arctic Health Resort.—A curious health resort is about to be established in Lapland, way beyond the Polar Circle, according to one of our Swedish exchanges. The intention of the Government is to erect a sanitarium on the shores of Lake Torne, a long and beautiful sheet of water at Wassijauve, the end of the Ofote Railroad. The latter, by the way, is in itself a curious institution in that in a distance of 121 miles it boasts of only one solitary station. This is not anywhere near any human habitation, but right on the line between Sweden and Norway, and it was erected only for the requirements of the Customs Office. The sanitarium would be an ideal one for people with weak nerves who need absolute rest. Aside from the small settlement at Wassijauve the country is absolutely void of any signs of human existence, except for a few Laplanders who, with their herds of reindeer, pass through once in a while. Guests at the Arctic sanitarium will have for their only object of interest, aside from the scenery, a scientific station which has been erected by the Government out of funds subscribed privately by scientists and laymen interested in the object of the station. The observations and investigations to be conducted here will be various. In Summer biological, geological, botanical, entomological, and other researches will be made, while at all seasons meteorological, magnetic, and other observations are to be made. The station is a solidly built block-house containing seven rooms, and it is proposed to build the sanitarium in the same way.

Christian Science and the Law.—"No clear case of 'Christian Science' killing has reached the public attention in the East of late—a fact which may prove almost anything except that there haven't been any killings," says the *Times*. "Elsewhere, however, the 'healers' have been less successful in getting their victims quietly under ground, and there is peculiar interest in a case cautiously but comprehensibly reported by the papers in Portland, Ore. It seems that there the daughter, a child three years old, of one James MacKenzie accidentally poisoned herself with wintergreen oil that had been carelessly left within her reach after use for some domestic purpose. The father had been cured of a 'stomach trouble' by an Eddyite neighbor two years before, and therefore, when the baby grew pale and still he sent for the convenient wizard. The usual mummeries were performed and the usual cure announced. Later in the night it became obvious even to a 'Christian Science' father that the child was dying, and he sent for a doctor. At the subsequent inquest the doctor testified that it was probably too late to save the baby's life, even when the wizard was called in. That contented the Coroner's jury, and it brought in a short, safe verdict of accidental death by poison self-administered. Thereupon there was great joy in the ranks of the deniers, and their local spokesman gravely proclaimed that from the testimony given at the inquest it was evident that 'Christian Science' had done more for the poisoned child than materia medica, whatever that may mean, was able to accomplish! Well, the little girl did live for some time after the incantations were chanted over her, and did die soon after a regular physician took the case. The argument is certainly a strong one—for imbeciles. It is a little queer, though, that the wizard failed, since he declared at the inquest that 'Christian Science' is easily effectual in all poisoning cases, and that he had saved one of his own children from the effects of a big dose of carbolic acid. It is really a wonder that the jury didn't hold the doctor to trial for manslaughter, if not for outright murder."

OBITUARY.

Dr. John Mercer Adler died of apoplexy in Devon, near Philadelphia, on February 11. He was seventy-six years old, and was one of the most prominent medical, literary, and art representatives in the city. Dr. Adler was born in Georgetown, D. C., and was edu-

cated in Georgetown College and Princeton University. Studying medicine at Columbia University, he was graduated with the class of 1847. Immediately after this he went to Colon, being connected with the Panama Railroad. Three years later he returned to this country, going to Davenport, Ia., as chief physician of the Military Hospital there, and was in charge during the entire Civil War. With the close of the war he came to Philadelphia. He was prominently connected with a number of leading medical societies, was the author of medical works, and was also actively engaged in life insurance organizations.

Dr. Max G. Rafael, who served as a surgeon in the Union navy during the Civil War and who was formerly a Deputy Coroner, died suddenly last week of apoplexy. He was in his sixty-eighth year. Dr. Rafael was born at Salem, in the Province of Baden, Germany. He came to this country at an early age and studied medicine at the Humboldt College, St. Louis. When the Civil War broke out he was commissioned a surgeon in the navy and served under Admirals Farragut and Porter. At the close of the war he began to practice medicine in New York. He was a deputy under Coroner Brady.

Dr. Emil Alexander de Schweinitz, Chief of Division in the Department of Agriculture and a noted bacteriologist, in which science, although yet a comparatively young man, he had made many original investigations, died in Washington last Monday of uremia. In recent years he had been Dean of the Medical School of the Columbian University. He was born at Salem, N. C., Jan. 18, 1866, being the son of Bishop E. A. de Schweinitz. He studied at Nazareth Hall and Bethlehem, Pa., and was graduated from the University of North Carolina in 1882, afterward receiving the degree of Doctor of Philosophy at Göttingen, Germany, and of Doctor of Medicine from the Columbian University. He was United States delegate to the Fourth International Congress on Tuberculosis at Paris in 1898, and in Berlin the following year. He held the same appointment to the International Medical Congress and Congress for Hygiene at Paris in 1900, and published many papers on bacteria, disinfectants and hygienic problems, and on the various antitoxins, tuberculosis being perhaps his especial study. He was a member of the Metropolitan, Cosmos, and Chevy Clubs, and of various scientific, chemical, and bacteriological societies, both American and foreign.

Dr. August Kreibiel, of New York, died last week. He was born in Bavaria, Germany, in 1839, and came to America in 1854. He returned to Germany and studied medicine in the University of Würzburg and was graduated. He again came to America and for twenty-five years was actively engaged in practice in this city, returning fifteen years ago.

Dr. Frank S. Bok, a prominent physician and Odd Fellow, of Pulaski, and Coroner of Oswego county, N. Y., for ten years, died in Oswego last week from pneumonia, aged thirty-six years.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, January 29.

PHYSICAL DETERIORATION OF THE BRITISH PEOPLE—THE LIGHT CURE IN LONDON—THE MENTAL AND MORAL EFFECTS OF THE SOUTH AFRICAN WAR—AN ANTI-CIGARETTE CRUSADE—NURSES FOR SICK DOGS.

As has been mentioned in previous letters, the British people have recently awakened to the fact that the standard of national physique is seriously deteriorating. This is shown by the large proportion of stunted and weedy lads found among those who offer themselves for enlistment in the army, and the vast amount of disease and deformity among the rising generation in populous cities pent. It is tolerably certain that unless the *urbipetal* tendency of the men and women who in a physical sense form the backbone of our population can be checked, and unless wholesomer conditions of life can be provided for the denizens of our town slums, the British people will in a century or two, perhaps less, degenerate into a race of sickly dwarfs, with the marks of inherited disease and depraved habits writ large upon them. Even amid the din of the great fiscal fight the voices of some who are striving to find a means of preventing a national danger have reached the ears of the powers that be. A special committee is now sitting and taking evidence on the subject. But such committees are mere safety valves for the Government in ebullitions of popular feeling. By the time the Committee has brought its labors to a close, the excitement has probably died down, and the report is quietly relegated to one of the pigeonholes where so many schemes of reform repose, as in a limbo of stillborn souls. It appears to be intended that the committee shall play the part of John the Baptist by preparing the way for a Royal Commission. But Royal Commissions, too, are often mere Greek choruses, proclaiming moral sentiment and giving good advice to which no one pays attention. A more hopeful sign is that the medical profession has been aroused to action in the matter. A petition has been drawn up and has already been signed by more than 8,000 medical practitioners, including Sir William Broadbent, Sir Lauder Brunton, Sir Thomas Barlow, Sir Victor Horsley, Sir William Macewen, Sir Henry Thompson, Sir Samuel Wilks, and the Presidents of the Royal Colleges of Physicians and Surgeons, which it is intended to present to the Central Educational Authorities of the United Kingdom. These authorities are urged to consider "whether it would not be possible to include in the curricula of the elementary schools, and to encourage in secondary schools, such teaching as may, without developing any tendency to what is unwholesome, lead children to appreciate at their true value healthful bodily conditions as regards cleanliness, pure air, food, drink, etc." Attention is called to what is already being done in this way in English-speaking countries, especially in the United States. It is pointed out that much of the degeneracy, disease and accident with which medical men have to deal is directly or indirectly due to use of alcohol. Inasmuch as a widespread ignorance prevails concerning not only the nature and properties of that substance, but also its effects on the body and mind, the educational authorities are urged to include in the school teaching of hygiene elementary instruction at an early age on the nature and effects of alcohol. The intention of the petition is admirable, but a cynical critic might say that it leaves out of account the innate depravity of what Matthew Arnold called "the average sensual man." It is stated in the petition that about twenty-two million children are being educated under this system in the United States; it would be interesting to learn that the amount of drunkenness has been appreciably reduced in consequence. It may be said that we must wait till the next generation before we can estimate the practical effect of the teaching. But in this country it has not been found that the diffusion of education has greatly reduced either vice or crime. A fierce struggle has been made to retain religious instruction in the program of elementary schools, but this has had no perceptible influence on the growth of indifference in regard to re-

ligious belief and practice in the working classes which, according to the testimony of all observers, is a fact that Carlyle, if he were to rewrite his famous essay, would place among the "characteristics" of our time. A knowledge of the effects of alcohol on the body, even if it could be given in any real sense to young children, would probably have no more effect in practice than a knowledge of the evil effects of immoral acts of other kinds has on the conduct of the majority of young men. The true remedy, it seems to me, is to be found in the State interference which Herbert Spencer taught us to view with such suspicion, but which in a matter so nearly affecting the welfare and even the existence of the nation, is surely justifiable even from the standpoint of abstract philosophy. Already the State does much for the children of the poor; and if they are not merely poor, but criminal, it takes them in hand altogether and brings them up in institutions away from the corrupting influences of their home environment. In the formation of habits of self-restraint and the development of a sense of moral responsibility lies the hope of the production of useful citizens out of the raw material that now goes to the making of degenerates. Early education in State institutions, followed by compulsory service in the army or navy, would do more to check the deterioration of the British people than the teaching of hygienic maxims to children who see them defiantly disregarded in every act of life by those around them.

The prospectus of a Light Cure and Therapeutic Institute was recently issued. The purpose of the Institute was stated to be to provide London "with greater facilities for electrical treatment than are at present available at the hospitals." The capital was said to be $60,000, which, considering the heavy expense of installing Finsen, Roentgen and similar apparatus, strikes one as very inadequate for the purpose. It is not apparent whether the scheme is intended to be partly charitable, or a manifestation of philanthropy at 5 per cent. To-day comes an announcement of another enterprise of the same kind. A "Red Cross" Light Cure and Electrical Institute is said to have been established in a fashionable quarter of London. The promoters say "We shall expect patients to be sent to us just as they are sent to Bath or Wiesbaden by their own medical men who know the value of this wonderful cure." It may be gathered that these institutes are to be run by lay directors, who may or may not employ a medical practitioner to look after the patients. Often such establishments induce a member of the medical profession whose poverty, but not his will, consents to the degrading association; sometimes they hire a man whose name has been struck off the Register for professional misconduct. There is a "boom" in light here, for which the London Hospital is largely responsible. The Queen some years ago presented a Finsen lamp to that institution, a circumstance which the very wide-awake Governors took care to advertise early and often. They have gone on doing so ever since. I see in the *Westminster Gazette* of this day a statement that the London Hospital has now an installation of eight lamps with thirteen nurses told off to give their exclusive attention to the working of them. "Great results have been obtained, and patients have come from all parts of England to be cured." Similar statements are made in the newspapers from time to time, evidently with the intention of creating an impression in the public mind that the London Hospital is the true shrine of Light, where alone sufferers from lupus can hope for cure. The credulous public is assured that the treatment is *certain* and that it is *absolutely painless*—both statements, as all who know anything of the subject are well aware, being absolutely false. The "great results" referred to have to be taken on faith, as no authentic record of them has so far been given to the world. From what one hears, it would seem that the "greatness" of the results lies in the value got out of them as advertisements, rather than in the good done to the patients. Special departments for the light treatment have now been established in many hospitals, both in London and in the provinces. The results of the method as carried out in this country, however, are by no means so brilliant as those reported by Finsen and his colleagues at the Lys Institute at Copenhagen. The difference may partly be explained by the difficulty of getting English nurses to give themselves with sufficient devotion to work, which is not only tedious, but trying to the nervous system. This, however, is not the whole secret, for at the private institution under the direction of the well-known dermatologist, Mr. Malcolm Morris, who was the real pioneer of the method in England, the treatment is in the hands of a most capable Danish nurse, trained at Copenhagen; nevertheless, the results—which Morris and his assistant Dore have published with commendable frankness—though fairly satisfactory, will not bear comparison with those claimed by the Danish physicians.

To the January number of the *Journal of Mental Science*, just published, Dr. R. S. Stewart, of the Glamorgan County Asylum, contributes a paper on the mental and moral effects of the South African War on the British people. During the early months when news of defeats and what Lord Roberts afterward called "regrettable incidents" came thick and fast, the emotions felt by us were naturally extremely painful, but there was no note of despondency, and with the spirit of old Rome the nation was determined that the republic should suffer no detriment. At that time there was a notable decrease in the amount of crime of all kinds throughout the United Kingdom, showing an improvement of moral tone in the nation. A "disinclination to matrimony" was also noticeable in the dark days of Ladysmith, Maggersfontein, Colenso and Spion Kop. The national depression even affected the birth-rate; the annual reports of the Registrars-General for both England and Scotland for 1900 contain the statement that the birth-rate for that year was the lowest ever recorded. From a large mass of statistics which he has collected, Dr. Stewart concludes that while the war cloud lay heavy and black over the British people, the nation, as a whole, had its criminal propensities checked; there was a "lessened disposition toward all forms of self-indulgence, a heightening of the respect for the lives and property of others, and a lessened disposition to shirk the troubles and responsibilities of life." Gradually, however, the effect produced by our reverses passed away until by the end of the year it had vanished, and, morally speaking, our last state was worse than our first. I confess that Dr. Stewart's figures do not seem to me to prove much. But the most superficial observer could scarcely have failed to notice that the war—especially when the turn of the tide came—had a decidedly brutalizing tendency not only on the mob, but on many persons of education.

A manifesto bearing the signatures of many leading medical men—among them being Mr. John Tweedy, President of the Royal College of Surgeons of England—as well as bishops, Members of Parliament, and headmasters of schools, has recently been issued with the object of calling the attention of the public to the evils of cigarette-smoking by children. Reference is made to the great increase among the young in recent years of a habit "which is undoubtedly doing much to undermine the health and ruin the character of many English

boys in the various grades of society." The hope is expressed that every possible effort will be made to deal with what the signatories of the manifesto believe to be a very serious hindrance to the young life of the nation. Almost simultaneously with the issue of this document comes the announcement that there is to be a crusade against the cigarette in Birmingham where a conference on the subject is being held this day (January 29). The movement has the support of many leading members of the medical profession in Birmingham.

The professions open to women in this country are already overstocked, and "bachelor girls" are looking out for fresh fields and pastures new. Those who have a vocation for nursing and think the conditions of admission to that profession too arduous may find an outlet for their natural aptitude and energies as ministering angels in the tending of sick dogs. In the eyes of a considerable section of the British public the comfort of a dog is of considerably greater value than a human life; ladies who take up this interesting branch of nursing will, therefore, have the satisfaction of knowing that they have the privilege of doing what many people believe to be the noblest work that it is given to a mere human being to do. The Dogs' Protection League some time ago established what is virtually a hospital for dogs. A visit to the kennels, we are assured, is like walking through the ward of a hospital, for fair nurses are in constant attendance on the canine invalids, who lie in swaddling clothes, or if convalescent, are allowed to go about the "ward." An official of this philocynic institution described his patients as being "as bad as human beings." "Some of them," he said, "have to be nursed all night long, or they would tear away their clothes and do themselves any amount of harm." The League has, it is stated, received thousands of dogs since it began. It has always a staff of trained nurses in attendance, and the "hospital" is under the direct supervision of two well-known veterinary surgeons. A lady who wishes to adopt the profession of a dog nurse is taken on probation and receives a thorough training in the speciality. Then she goes out to whatever cases she may be called to. She is taught how to prescribe for a sick dog, physic it, diet it, and clothe it, in fact, how to adapt ordinary hospital nursing to the relief and care of sick dogs. Dog nursing is said to be extremely popular among ladies, and there is nothing at all improbable in the statement.

TYPHOID EPIDEMIOLOGY.

To the Editor of the Medical News:

Dear Sir: In view of the frequency with which typhoid epidemics have of late appeared in various parts of the United States, and of the alarming proportions which some of them have assumed, it has seemed to me that it might be of interest to your readers to learn of the manner in which these epidemics are being combatted in Germany. I had the good fortune to be appointed "Assistent" in a laboratory established last summer for the specific purpose of studying, and, if possible, of cutting short the epidemic which was at that time raging in one of the districts of Elsass, and thus had an opportunity of observing, at very close quarters, the methods and theories of the movement against typhoid in Germany. That it is really a "movement," a national movement, undertaken in the spirit of a German army campaign, lends it an interest and an importance which hardly attach to the sporadic skirmishes with local epidemics, as they are carried on in all other countries, including our own, organized generally in great haste and frequently under quite unfavorable circumstances. In Germany, however, the entire machinery of the Imperial Government has been set in motion, and a very considerable fund has been made available, to carry on a continuous and well-planned crusade against the ravages of the disease; that the entire organization is under the control of such men as Koch, Flügge, and the Surgeon-General of the Army, gives some notion of its intention and of its efficiency.

It was toward the middle of July that I first received intimation through the Professors in the University of Strassburg that I might have the regular position of Assistent in a "field-laboratory"—or "fliegende Station," as they called it, on the analogy of an easily moved, temporary, army-garrison—which was soon to be established in Diemeringen, a village about 2½ hours from Strassburg. I had already had an opportunity of seeing how the work was conducted in the large permanent stations, with well equipped laboratories, situated in the midst of a great city, such as was the Hygienic Institute of the University of Strassburg. Of these there were at that time four in Germany, namely, one in Trier, presided over by Prof. Frosch; in Metz, by Conradi; in Saarbrücken, by von Drigalski; and in Strassburg, by Profs. Forster and Ernst Levy, all of them with perfect facilities, and a large body of assistants. Under such circumstances, the work differed only in details from that carried on by efficient boards of health in all large advanced cities. The conditions which were to be confronted by the new station in Diemeringen were, however, of an entirely different kind. Here was a squalid country village, of perhaps a thousand inhabitants, situated in one of the most neglected regions of the Empire, Elsass, which has alternately been the stepdaughter either of Germany or of France. Around this village, typhoid had become epidemic, and in some of the hamlets had attained the proportions almost of a scourge, or a pest, inasmuch as ten per cent. of the inhabitants were suffering from the infection. This was an opportunity for which the large plan on which the movement was organized had made provision, although no occasion had previously arisen to test its practicability. Diemeringen was to be the first, experimental, flying station. The epidemiology and bacteriology of the disease were to be worked out in an improvised laboratory on the spot, but according to exactly the same requirements and regulations as had been prescribed for the chief stations in the larger cities. That these requirements were by no means trivial will subsequently become evident. I was very much interested in seeing how this experiment would turn out, and therefore I determined to accept the position proffered me.

About a week was consumed in arranging all the preliminaries. A laboratory "Diener" had to be engaged, and taught the rudiments of his work. An initial stock of culture media had to be made up for use during the first few days. And, most important of all, a list of necessary articles had to be prepared, and sent to the firm of Lautenschläger, in Berlin, who were to forward the supplies as rapidly as possible to the seat of operations. Finally, however, everything had been arranged, and on one afternoon in the early days of August we set out from Strassburg, and betook ourselves to Diemeringen. Our "staff" consisted of Dr. Kirstein, first assistant to Prof. Flügge in Breslau, and previously assistant to Eberth in Halle, myself, and the laboratory Diener. We reached the village late that night, and it made upon me, at least, an impression which I shall hardly forget. There was neither carriage nor wagon to meet us; however, my host of the "Eisenbahn Hotel" had provided a man with a wheelbarrow, in which our belongings were trundled up to the hostelry. So, through the long,

narrow, winding street of Diemeringen, its only thoroughfare, we wended our way. On each side of us were the low shanties, which expressed the poverty of the inhabitants, and from which issued occasionally the grunting and lowing of the beasts that shared them with their human owners.

Our work now began in earnest. The Government had leased for our use a fairly large building, with two floors and an attic, and this was dedicated to laboratory purposes. Our home was in the hotel. The house was sufficiently large to enable us to set aside one room for the secretorial work, which was considerable in amount, inasmuch as the details of every case had to be recorded and tabulated; another room for microscopic work; a third room for the sterilizers; another, which was fitted by the local plumbers with a rude sink, as a washroom; and, finally, one as a home for our animals. It took no little pains to get things to rights for the six weeks' stay which we proposed to make. Furniture had to be supplied by the carpenters, and was designed by Dr. Kirstein, to be as simple as possible, and, at the same time, to be easily portable, since it was expected that the station with all its supplies would be transferred from Diemeringen as soon as its work had been accomplished there, to some other typhoid center, as was, indeed, subsequently done. The laboratory equipment, which had been gotten together by Lautenschläger, at a cost of between 3,000 and 4,000 marks, was in its way ideal for the purpose. We had expected great difficulty with incubators and sterilizers, knowing that there was, of course, no gas in Diemeringen. For the dry and steam sterilizers, the firm provided two petroleum apparatuses, known as "Juwel," of a type commonly used in Germany in the kitchen. They are so designed that the vapor, and not the petroleum itself, ignites, and they maintain an extremely high degree of heat for a considerable time. Thus, the hot air sterilizer could be heated to 180° F. within fifteen to twenty minutes, and the steam sterilizer could be kept in constant operation for a whole day without refilling. The problem of maintaining a constant temperature in the incubator by means of a petroleum lamp would appear to be almost insurmountable, yet with the form of lamp furnished for this purpose by Lautenschläger, I venture to assert that there was not a variation of three degrees during the whole period of our work. All the apparatus was of the most modern type. Our microscopes were two Zeiss instruments, of the type known as field microscopes, with a case of leather, which could be slung over the shoulder. It is needless to enter into all the details of laboratory supplies; suffice it to say that every need had been most anxiously foreseen and most carefully provided for.

Thus, within a very few days, we were in complete working trim, and in the full blast of our work. The problems and the tasks which confronted us were chiefly of two kinds—epidemiological and bacteriological, and I shall so divide the description of our work. The epidemiological investigation was done by Dr. Kirstein, whereas the greater part of the bacteriological work was done by myself.

In Diemeringen itself, there were, fortunately for us, no cases of typhoid. In at least four of the neighboring villages, however, the disease had broken out, and in Rathsweiler, about three miles away, it had stricken fully ten per cent. of the peasants. The system on which the investigation was organized had been planned in Berlin, and, it is safe to say, was such as could be inaugurated in no other country on earth. Besides ourselves, the machinery which was set in motion in order to render our work as complete as possible, comprise the so-called Bezirksarzt or Kreisarzt, the local physicians, the mayors, and the police. To one who is not acquainted with German conditions, especially such as prevail in the Reichsländer, such as Elsass and Lothringen, a few words of explanation are necessary for an understanding of the powers of these functionaries. The Kreisarzt is a physician appointed and salaried by the State, with functions somewhat similar to those of local boards of health, with the difference that his work is governed and controlled by a central bureau. The physicians stand to their patients in a relation similar to that which maintains elsewhere, but in an altogether different relation to the State. As is the case with so many other professions in Germany—notaries, apothecaries, and others—their number within a given area of territory is limited by statute; this fact tends to insure their practice and prosperity, but renders each physician rather dependent on the good will of the governing power. If he prove in any way disagreeable his position may be rendered very unpleasant, or the number of possible competitors may be increased, to his detriment. Thus the entire local medical profession could be induced to work in harmony with the ends of our investigation. It was enacted that every physician should immediately report every case of typhoid which came under his notice, every suspicious case, which manifested headache, malaise, or diarrhea, to the Kreisarzt of the district. The Kreisarzt was at once to forward his information to the Untersuchungsamt, our laboratory station, and then either he or the station was to take measures leading to the bacteriological identification of the case. In all cases occurring in the villages nearby, we procured the necessary material—feces, blood, and, in cases of pneumotyphus, sputum—in person; if this were inconvenient, the physician was requested to send us samples by the earliest mail, for which purpose specially contrived receptacles were put at his disposal. Of prime importance, of course, is the material for a Widal test, and for this purpose small bottles with rubber stoppers were provided, which could be inclosed in a special form of wooden box, and so safely transmitted through the mail; similar bottles, carefully secured against leakage were provided for feces. The bottles for feces were provided with a cork stopper, into which was fastened a small metal spoon, which reached about half way down to the bottom of the bottle. Bottle and cork were first sterilized. The fecal material was to be packed into the bottle by means of the spoon, and, in the subsequent examination at the laboratory, the contents were removed by a sterilized platinum loop. I mention these details in order to show what consummate care was taken to avoid even such a common accident as the chance contamination of the suspected feces. Physicians were requested to send at least 5 c.c. of blood, inasmuch as it was the rule to control the microscopical by the biological test. All of these regulations made it fairly certain that no case of typhoid could escape detection, and, from an epidemiological standpoint, this was an extremely important consideration. The relation of the mayor and police board to our work consisted chiefly in the enforcement of the necessary general hygienic measures, as will be subsequently detailed.

The first problem, and, it may be said, the chief epidemiological problem which had to be solved, was the question of the origin of the epidemic. I believe it to be not quite generally known in America that the present movement in Germany is based upon a theory which represents a violent break with the typhoid traditions of the past. It has long been, and is, at present, very generally believed that epidemics of typhoid fever are nothing more nor less than water infections. Indeed,

at the recent Städteausstellung in Dresden, in which an entire building was devoted to epidemiology, comparative statistics of previous typhoid epidemics seemed to show that at least 97 per cent. of these could be traced to contamination of the water supply, or of the milk, which amounts practically to the same thing. Nevertheless, an undercurrent of revolt against this theory has never been wanting. It has always been recognized that a certain number of cases get their infections, not from a common water-supply, but from direct contact with other victims of the disease. The most common example of this kind of infection is furnished by the nurses, who in "model" hospitals, such as that in Hamburg, become infected in a ratio of two per cent., while in some hospitals, such as the Prussian military lazarets, the infections may reach 8 or 10 per cent. Moreover, occasional epidemics have arisen, in which it has seemed impossible to lay the blame at the door of the water supply, as in that which occurred in a French garrison, if I remember rightly, in Algeria, in 1901, and which was attributed to the distribution by a wind storm of typhoid germs, which were supposed to have lain dormant in dried-up dung-heaps on a neighboring plain. Fanciful as this individual explanation may seem, the fact remains that the improvement in water supply does not appear to have worked with the same degree of magic as in the case of cholera. There is, for example, no case in typhoid literature which shows the same wonderful coincidence of the area of disease with that of a contaminated water supply, as did the Hamburg-Altona epidemic of cholera. Moreover, improvement of water supply has notoriously not exterminated typhoid. Thus, the city of Paris, which has of late years become a model in this respect, has still presented minor localized epidemics of the disease, a fact which could only be brought into harmony with the dominant theory by advancing the still more questionable hypothesis of contamination by "sources Vanelusiennes," or underground streams coming from a distant surface source, as suggested by Chantemesse. A new character has been given to all these problems by the recent announcement of Koch, that all typhoid epidemics must be considered in the light of an infection from man to man. The theory is, it must be admitted, not original with Koch. Musehold, at present Ober-Stabsarzt in the garrison at Strassburg, was the first, I believe, to assert that a certain garrison-infection could only be explained on this basis, and to combat it along lines logically deducible from this hypothesis. But to Koch, as in so many other things, belongs the credit of having firmly and uncompromisingly indicated the general principle. He maintains that the typhoid bacillus is for all practical purposes to be regarded as an "obligate parasit," that it does not maintain its existence outside of the body for any considerable time, and, consequently, that infections are practically from the excreta of one victim to the mouth of the next.

I am well aware that bacteriologists will have much to urge against the very fundamental premises of this theory of Koch's. One need only consult any complete article on the biology of the typhoid bacillus, such as Neumann's in Kolle and Wasserman's Handbuch, in order to convince himself that it is undoubtedly possible for the germs in question to live for a considerable period outside of the body. This, however, is not the point at issue, which must be decided by practical hygienists and clinicians rather than by the bacteriologists. It is simply the contention of Koch that the vast majority of typhoid infections do, as a fact, occur without the agency of a contaminated water or milk supply. It may very well be that his statement is too sweeping; one can hardly believe that the many epidemics which have, apparently with consummate care, been traced to the water supply, should all have been misinterpreted and misunderstood. Nevertheless, it is well to keep in mind that there are few problems more difficult and delicate than the unraveling of an epidemic, and the determination of such cases as have, presumably, received their infection from the water-supply as opposed to such as have received it by direct infection. The crux of the whole question lies in the fact that a careful investigation generally reveals that either mode of infection might, in almost any set of cases, be held responsible. The current of personal intercourse within a community, with all the possibilities which it furnishes for the direct conveyance and transference of the germs of the disease, is as all-pervading and as far-reaching as is the underground current of water. An honest investigator is, therefore, driven to rely wholly on such circumstantial evidence as the *course* and *progression* of an epidemic, which, as I have said, constitutes essentially a non-bacteriological problem. Certainly it is a very remarkable fact that the greatest clinicians of the "ante-Koch" era of medicine received for the most part an altogether different impression of typhoid epidemics from that which subsequently became established. Thus, the great Trousseau, in his collected clinical lectures, recites the history of a large number of epidemics, which seemed undeniably to have traveled from person to person. Most remarkable in this respect was the epidemic of 1855, in the village of Trombern, in which, says Trousseau, it was "a striking fact that the first case appeared in the first house to the northwest of the village, and that the epidemic then advanced step by step, from house to house, until it finally reached the southwestern extremity of the village. I have, however, wandered very far from my purpose, which was neither to defend nor attack any theory of typhoid, but to recite the facts as I observed them in Diemeringen and its vicinity. Be the theories as they may, I am very sure that the epidemics which we had occasion to observe illustrated the potency of contact infection to an extraordinary degree. Personally, I feel convinced therefrom that there will prove to be a very large element of truth in the statement of Koch, and that, just in such country epidemics as we had to study, contact-infection will prove to be at least a very important factor. I come now to a brief description of the epidemic in Rathsweiler, which will show in how far my assertions are justifiable. We may then best consider what constitutes, and contributes to contact-infection, under what circumstances it is apt to become effective, and how it may best be combated.

(To be Continued.)

SOCIETY PROCEEDINGS.

NEW YORK PATHOLOGICAL SOCIETY.

Regular Meeting, held December 9, 1903.

The President, William H. Park, M.D., in the Chair.

Notes on a Number of Mallein Reactions.—Dr. Letchworth Smith said it was the purpose of these notes to present as briefly as possible some of the results of examinations of a number of horses killed during the summer after having been tested by mallein. A reaction to mallein included three points: (1) General reaction—dejected appearance, staring coat, etc. (2) Local reaction—appearance of tender swelling lasting several days. (3) Rise of temperature. According to the Health Department Circular of Information regarding the use of mallein, this was "from 2.7° to 7.2° F.," while French and German authorities insist it

should be at least 3.6° F. to 2° C. The list of cases given did not include all the horses killed, but those which fulfilled the following conditions: (1) Tested by mallein during the months of March, April, May and June, 1903, and notes of the tests recorded; (2) condemned as result of tests; (3) autopsied and bacteriologically examined by Dr. Schwarz, Dr. Weil or Dr. Smith. The results were interesting on account of the temperatures, the part of the mallein reaction which usually claimed the greater share of attention. The temperature was taken five times in the twenty-four hours preceding injection of mallein and five times following it. The mallein was made by Ravenel's method. In estimating the rise of temperature during these tests, the average taken before the injection was compared with the average taken after it, rather than by comparison of the highest temperatures reached in each case. Of the 43 cases with conditions as above mentioned, 8 had shown a rise of 2° C. or more in temperature. Of these, 3 showed lesions interpreted as glanders, besides yielding the glanders bacillus; 2 showed indications of glanders, but the bacillus could not be isolated. Three seemed normal. In 22 cases of the 43, there was a rise of 1 to 2° C. Six of these were bacteriologically and pathologically proven to be glanders. Seven were pathologically positive. In nine cases there were no indications of glanders. In the 13 remaining cases the temperature rose less than 1° C. Four yielded glanders bacillus, 5 showed suspicious lesions and 4 were negative. Even in the cases in which there was a marked rise of temperature, more than one-third showed very doubtful lesions, or none whatever. As the foreign authorities would lead one to expect, 13 cases with temperature changes less than 2° C. were negative. But in the attempt to "stamp out" glanders, the destruction of normal horses was no more important than the mistake of passing over one having he disease. If the conservative course had been followed—of considering the cases negative if they failed to show a rise of temperature of 2° C.—10 horses from which the bacillus was recovered and 12 others which were very probably cases of glanders, would have remained alive, and been a possible source of infection. The speaker regretted that more reliance could not be placed on the negative reactions. Some cases put down as negative might have proven positive bacteriologically if the destruction of the horses could have been satisfactorily managed. It was impossible to get possession of material as soon as desired.

Dr. Smith spoke of the lack of knowledge of lesions which simulate glanders. The experience of the summer supported the position of those who consider mallein a favorable diagnostic agent in suspected cases of glanders rather than those who condemn it. Whether or not under ordinary circumstances the actual destruction of horses, which showed no symptoms of glanders except a reaction to mallein is justifiable, was still an open question. The later observations of Nocard, Babes and other authorities on the curability of the disease tended toward the more conservative idea of isolation until the appearance of more definite evidences that the animal is useless.

An Unusual Case of Multiple Neuritis.—This case was reported by Dr. Harlow Brooks. The patient was a woman, fifty years of age, born in Russia. Apparently there was no tuberculous, specific or neuritic taint in the family. At an early age she began to drink whisky steadily, but never to the point of intoxication. She also drank a little beer, tea and coffee, but not to excess. She married when twenty years of age, and from this time forward had various symptoms which reappeared from time to time. Her ankles became painful and swollen after exertion, pain disappearing after rest. She had attacks of diarrhea following periods of constipation, the latter lasting six or seven days. At forty years of age she was frightened and after this had headache, which lasted for a year and a half, but was relieved by domestic remedies. At the age of forty-one her ankles became so swollen and painful that walking was impossible, and she remained in bed for a time, after which she was able to walk about again. Because of painful callosities on the sole of her feet, she walked on the heels, which gave her a peculiar gait, which still persists at the age of fifty years. Two and a half years ago she noticed some anesthesia of the soles of the feet. This was not permanent, but remained for a week or two, and then disappeared only to return again. Two years before her admission she had lumbago, with severe and persistent pains in the wrist. She lost control of the bladder for nine months, when she recovered completely. During her last illness of nine months' duration, she suffered from pain in the larger joints of the body, was very weak, could do no housework, and remained in bed much of the time. She had no control over urination and defecation. Pains in the back were very severe, also pains in feet, arms and shoulders, when she could not raise either her hands or feet. After six months in bed with intervals of improvemnt, she was able to sit up without help. When examined at the hospital the muscular dexterity was impaired, myotactic irritability was wavelike, there was no perceptible enlargement of the superficial lymph-nodes. She showed no mental weakness, was good natured, and complained very little of the pain from which she apparently suffered. The muscles were flabby and normal in volume, except for a slight wasting of the small muscles of the right thumb. Sensibility as to pain, touch and temperature normal. When two fingers were placed upon the arm, she recognized four, usually increasing rather than decreasing the number of points. Reflexes were exaggerated, motor power diminished. Slight foot drop was noticed when the patient was in bed. The patient developed a bed sore, grew rapidly worse and died. Postmortem showed the lesions of a long-standing case of alcoholism of the chronic type. The brain was abnormally firm. The spinal cord was firm in spots in other places it was soft. No apparent changes in the retina. Anatomical diagnosis was peripheral neuritis probably of alcoholic origin. There was interstitial hyperplasia in all the organs. In the brain, spinal cord and nerve roots, it was found that the cortical fibers coming from the large pyramidal cells of the frontal and parietal regions of the cortex were extensively degenerated. The fibers were also degenerated in the internal capsule, the medulla and the spinal cord showed a marked descending degeneration most marked in the crossed pyramidal tracts. As she expected, degeneration of the posterior tracts was found, but it was more extensive than anticipated. There were, however, no distinct areas of sclerosis. The posterior root ganglia showed cytoclastic changes and both posterior and anterior nerve roots were extensively degenerated. In the peripheral nerves there were interstitial and parenchymatous degenerations more prominent in the smaller trunks, less so in the larger. Presence of the descending degenerations was most interesting. These degenerations were present without marked mental change as though the motor fibers were particularly affected, and yet in the so-called psychic areas sections showed some degenerated fibers. The speaker thought it rare in cases of alcoholism producing degeneration in the brain, cord and peripheral nerves, to find the descending degeneration fully as marked as the ascending changes.

He thought the lack of knowledge of these brain changes was due to the fact that observers had been satisfied on finding the changes in the peripheral nerves and did not search further for alterations in the brain.

Dr. M. G. Schlapp, in the discussion, said that two years ago he had shown a case of so-called alcoholic neuritis in combination with mental symptoms (Korsakow's syndrome) to the Pathological Society, in which there had been marked changes in the spinal cord and medulla. The brain of this case had not been examined up to the time of the presentation, but later he examined and found changes throughout the cortex. This case differed from the one of Dr. Brooks, in that the mental symptoms were very marked. The point brought out by Dr. Brooks that these changes had not been observed in similar cases of alcoholic poisoning before, is very likely due to the fact that in examining these cases former observers did not use a method whereby acute degenerative changes, such as are found in alcoholic poisoning, are made visible. These changes are demonstrated by the Marchi method. The lesion as a rule is the result of an acute or subacute condition. It does not involve whole tracts, but only groups of fibers in certain tracts, particularly the fibers in the posterior root zones of the spinal cord, and the intramedullary fibers of the sensory cranial nerves. The speaker agreed with Dr. Brooks, and wishes to lay special stress upon the statement, that it is very likely that in all those cases of so-called alcoholic neuritis, the lesion is not confined to the peripheral nerves, but is also found in the central nervous system; in fact, in all the cases examined by the speaker, five cases of alcoholic neuritis with mental symptoms (Korsakow's syndrome) the lesion was more marked in the cord or brain than in the peripheral nerves.

A Patent Foramen Ovale and a Case of Multiple Serositis.—These cases were demonstrated by Dr. J. E. Welch. In the first case the patient was an Italian boy of sixteen years, who could not give an account of himself in English. He had dyspnea and edema of the legs, which gradually spread over the body and became general. The principal symptom was great pain over the precardial region; so great that he requested another Italian in the ward to give him some instrument with which he might commit suicide. Autopsy showed heart greatly enlarged on the right side, hypertrophied and dilated. Deposit of recent fibrin over right auricle and ventricle and about apex. All valves were thickened, tricuspid and mitral to a much greater extent than the others. The patent foramen ovale was of enormous size—1½ inches in diameter; just beneath it was another and smaller opening.

In regard to the second case: In 1846 Van Deen reported a case with the following findings: Obliterating pericarditis, pleurisy with adhesions obliterating both pleural cavities. Inflammation of the peritoneal cavity causing general thickening of the peritoneum, with marked thickening over liver, spleen and the intestines. This case had constant ascites with edema of the legs subsequent to the ascites. Van Deen's theory was that the obliterating pericarditis was the primary lesion and that the inflammation spread to the pleural surface, thence to the abdominal cavity. Since then many cases have been reported. Dr. Wood, of Philadelphia, in the *American Journal of the Medical Sciences*, January, 1903, showed that a constant feature was an ascites, the serous membranes throughout thickened with obliterating pericarditis. The principal point is the fact that ascites appears before the edema in the legs in a great majority of cases. There is no change in the liver, except in a few cases that would account for the ascites. In the case Dr Welch reported, the patient was a stableman aged thirty-five years; was alcoholic; took five or six glasses of whisky a day, one or two before breakfast, and enormous quantities of beer. Had had gonorrhea several times. Twelve years ago had chancroids, followed by suppurating inguinal adenitis. Was never ill before. November 1, 1902, cramplike pains all over the body which soon localized in the upper part of the abdomen which became swollen and tender. Physical examination showed that he had ascites with swelling of the legs, the heart had a rapid, feeble action. There was some increase of tension in the arteries, which were small in volume. Somewhat cyanosed; no jaundice. Directly after admission to the hospital a general syphilitic rash broke out. He then admitted having had a hard chancre, which had healed five weeks previously. He was dismissed from the hospital December 12, 1902, feeling much improved, and was treated in the Dispensary until the first of March, 1903, when he began to have swelling of the abdomen, with pain; about two weeks later had dyspnea and edema of the legs. He entered Bellevue again on March 15, two or three weeks after his trouble began. A short time afterward he was tapped, and a large quantity of fluid was drawn, which was of the nature of a transudate. He was tapped at intervals until just before his death, which was in the early part of August, 1903. Autopsy showed (membranes of brain not examined, as permission to do so could not be obtained), obliterating pericarditis. The right pleural cavity contained firm, old adhesions, about the base of 300 c.c. of serum, the left contained firm adhesions to the posterior border of the lung, and about the base, three litres of serum. Had perihepatitis (sugar-coated liver), perisplenitis (sugar-coated spleen), and general diffuse thickening of the peritoneum. There were a few slender, firm, cordlike adhesions between diaphragm and upper surface of liver, both lobes; also between the stomach and transverse colon, tubercles in the lungs and in the bronchial lymph glands; few in the spleen, none in peritoneum or liver. Liver cirrhosed, inter and intralobular connective tissue. There were 4,000 c.c. of turbid serum in the peritoneal cavity. There was complete obliteration of the great omentum and gastrocolic omentum, and free communication between the greater and lesser peritoneal cavities. Cause of condition, probably alcoholism, syphilis and tuberculosis; tuberculosis in the peritoneum not included in this case. That is also given as a cause by some writers on the subject.

Dr. E. Libman, in the discussion, asked Dr. Welch if there had been any positive venous pulsation; the combination of a mitral insufficiency with an open foramen ovale usually produced it. He said he had looked up the records of the hospital; in the last hundred autopsies there had been thirteen cases in which the foramen ovale had been more or less open. They had occurred at all ages from three months to forty-four years, and had not shown any clinical symptoms that could be referred to the foramen ovale. Ordinarily this condition did not seem to produce clinical symptoms, unless combined with other congenital or acquired lesions, or particularly in infants with diseases of the lung causing interference with the circulation. In the case reported by Dr. Welch the opening was very much larger than he had ever seen.

Dr. Welch replied that there was a venous pulsation in the vessels of the neck and there was also a very distinctly pulsating liver.

Dr. Brooks said the case had been very carefully examined in the ward, and the lesion had not been classed as of the foramen ovale. The man arrived from the steamboat and diagnosis could not be made out. The trouble was thought to be a double mitral lesion and

possibly tricuspid. There were so many murmurs they could not be localized as coming from any one place.

Paratyphoid Infection.—Dr. George A. Tuttle reported a group of seven cases of paratyphoid infection, four of whom, a mother and three children, entered the Presbyterian Hospital. They were all taken ill about the same time with symptoms suggesting typhoid fever. Three of the cases recovered. The mother died. In no case was an agglutination reaction obtained with the typhoid bacillus. From the tissues of the patient who died, pure cultures were obtained of bacilli, which formed typical colonies when grown in the Hiss medium. They did not coagulate in milk nor produce indol. No gas was formed in lactose bouillon. They fermented glucose with the production of gas. They were motile and resembled morphologically typhoid bacilli, but there was no reaction to strongly agglutinating typhoid serum. The blood of this patient and that of the other three cases clumped four out of six specimens of paratyphoid organisms obtained from the Laboratory of the Board of Health from different sources. Examination in the fatal case showed that the lungs, heart and liver were normal. The gall-bladder contained a number of fairly large calculi, one of them forming a sort of ball valve in the cystic duct. The gall-bladder was filled with a viscid, light colored fluid. The wall was thickened and had evidently been the site of an old cholecystitis. The spleen was soft, pulpy, and weighed 6¾ ounces. The kidneys weighed 6¼ ounces each, with nothing to indicate any chronic disease. The cortex was pale and there was considerable congestion. The intestines showed Peyer's patches normal, except in the lower two inches just above the ileocecal valve. Here there were four or five small ulcers, the largest one, one-half inch in diameter. They were punched out and were rather deep, some reaching the peritoneal layer. The lower part of the small intestine and the entire large intestine were filled with blood. Living on the same floor with this family was another family of four persons. At least three of these people were taken ill in the same manner at about the same time. These two families lived on the top floor of a tenement house, and obtained water from a tank on the roof into which the water was pumped from the cellar. They obtained milk from different sources and it seemed probable that the water was at fault. However, it had been examined and nothing found. The blood from one of the cases in this second family was obtained through Dr. Park, and it gave a prompt agglutination reaction, with the paratyphoid bacilli isolated from the fatal case in a dilution of 1 to 60, but did not agglutinate with typhoid serum. This group of seven cases is considered as paratyphoid.

Dr. C. W. Field said he wished to say a word about the tank on the roof mentioned in Dr. Tuttle's report. It was built last year, and was made extra large, the owner thinking he might make a deal with the owner ot the next house, and have the four top floor tenants supplied with water from the same tank. This could not be done, and this large tank was pumped full, the water allowed to remain without freshening until all used. In this way when water was low, it became offensive, nearly black, filthy and dirty, as both families assert. The husband in the other family refused to drink it; he drank beer instead, and remained well. In this family there were five members, of whom three became ill. A man caller came frequently during the month of August and drank considerable water during evening. On October 7 he developed a disease which was diagnosed as typhoid in Yonkers. He recovered. He had temperature when taken ill of 104½° F. All symptoms corresponded closely with the group reported, and without doubt he had been infected from the same source as the others. All recovered within about four weeks from the beginning of the attack.

Dr. Park said the only people attacked were those who used the tank water. Out of a possible thirteen, eight became infected. There were seven or eight other families in the house, with no cases of the disease whatever.

Dr. Libman wanted to know what sort of serum was used which refused to agglutinate the bacilli from these cases, but did agglutinate typhoid? He wanted to know also what the reaction of the bacilli was in glucose media.

Dr. Tuttle replied that when it was found that the bacilli did not produce Widal with the ordinary typhoid, they were tested with the glucose medium. In twenty-four hours there was a very faint bubble of gas. In forty-eight hours there was abundant production of gas; no gas in lactose.

Dr. Brooks asked if the ulcers looked like typhoid, and what was the condition of the peritoneal lymph-nodes.

Dr. Tuttle replied that they looked like some typhoid ulcers, and that no observations had been made of the peritoneal lymph-nodes. In his experience Peyer's patches had been irregularly distributed in this neighborhood. There were punched out ulcers in the mucous membrane, with no evidence of Peyer's patch around them. If the patch had been there it was all gone. The ulcers were in just about the area where one would expect to find the patches—within two inches of the ileocecal valve. He also said in regard to the microscopic appearance of the bacteria in the hanging drop they did not look like typhoid bacilli, and did not act like them. They appeared to be shorter, often double and frequently were in long strings, almost like streptococci. After staining they looked like typhoid, but were markedly different in the hanging drop.

Dr. Park said the cases were interesting, as the woman who had died had been engaged in cleaning up a great many typhoid cultures at the Research Laboratory, and it had been suspected that she had become infected in the laboratory. If the disease had not been proven to be tank infection and paratyphoid it would have been hard to make it clear that she had not been careless in working at the Department of Health. This showed how misleading apparent evidence might be in many cases.

Precipitins.—Mr. J. P. Atkinson read a preliminary note on precipitins formed by injecting animals with globulin derived from normal horse serum and from horse serum containing diphtheria antitoxin. The experiments were devised to see whether in animals injected with the globulin of normal horse serum and with the globulin of diphtheric antitoxic horse serum were developed anti bodies which would act as a specific precipitin for normal horse serum globulin, and for the antitoxic horse serum globulin, respectively, thus affording a method for separating the active substance in diphtheria antitoxic serum from the inactive substance. Globulin solutions were prepared from normal and diphtheria antitoxic sera by precipitation with magnesium sulphate and were purified by solution and reprecipitation until free from serum albumin and finally were freed from magnesium sulphate by dialysis. Chloroform was used to prevent putrefaction. Two rabbits were selected for immunization, one being injected with the solution of normal globulin, the other with the solution of antitoxic globulin. After a number of injections had been given each rabbit they were bled and the sera from the clots were tested against

diphtheria antitoxic serum with the following interesting results:

Two samples of diphtheria antitoxin which had just recently come into the laboratory to be tested were diluted so that 1 c.cm. of the dilution contained one-tenth unit of anitoxin. Two portions of 5 c.cm. each were taken from each dilution and to them was added serum from each rabbit, so that the globulin in each antitoxic horse serum was acted on by what we may call an antinormal globulin serum and an antitoxin antiserum, which should react for both normal and antitoxic globulin. After precipitation had taken place the precipitates were filtered off. An amount corresponding to 1 c.cm. of the original serum dilution from each filtrate was mixed with ten fatal doses of diphtheria toxin and injected subcutaneously into guinea pigs. All the guinea-pigs died within forty-eight hours after inoculation.

The antitoxin dilutions were tested against diphtheria toxin, to make sure that without the presence of the rabbit sera these antitoxins would protect against ten fatal doses of diphtheria toxin. The toxin was also tested and found to be of the estimated strength. The action of both rabbit sera was again tested. In this experiment twice as much antitoxin as was necessary to protect against ten fatal doses of toxin was used, instead of the exact neutralization dilution. The result was the same. Both guinea-pigs injected died within forty-eight hours. It will be seen by these tests that a specific antibody differentiating between normal globulin and antitoxic globulin was not found, for the rabbit injected with normal globulin solution produced precipitating substances for the antitoxic globulin.

One would infer from the results of these tests that normal globulin and diphtheria antitoxic antiglobulin are affected by a common precipitin, while differing in the molecular arrangement through which neutralization of diphtheria toxin occurs. It also adds to the belief that diphtheria antitoxin is of a proteid nature. Experiments were made to determine whether he globulin precipiating serum would throw down the antioxin from the toxine antitoxin and leave the toxin free. It did not do this and thus showed that a strong combination existed between the toxin and the anitoxin. Whether the toxine antitoxin combination, as well as the free antitoxin was precipitated or whether it was left in solution is being now determined.

Dr. F. C. Wood said that he did not think it was justifiable in our present state of knowledge concerning the precipitins to expect that the reaction would be in any way sharply limited to the antitoxin. From his own experiments and those of others it had been shown that the blood of an animal immunized with a pure proteid, for instance, a serum albumin from human chest serum, would give a serum which precipitated not only human serum albumin, but globulin and even hemoglobin.

It was still doubtful whether the hemoglobin, for example, was actually precipitated by the antibody, or whether it was carried down mechanically with the precipitum from other proteids present. It seemed to him also that the assumption from precipitin tests alone that diphtheria antitoxin was of proteid nature lacked foundation, especially after the results obtained by Jacoby in isolating the toxic group from ricin. Apparently the toxin in this case, though it could be precipitated by means of neutral salts, yet was not of proteid nature, but only attached to the proteid molecule. The contradictory results obtained by Obermayer, Pick and Michaelis showed that there was much to be learned about the exact chemical nature of the precipitated substance.

THE NEW YORK ACADEMY OF MEDICINE.

Section on Diseases of Children.

Regular Monthly Meeting, held December 10, 1903.

The President, Henry Heiman, M.D., in the Chair.

Hypertrophic Cirrhosis in a Child.—Dr. Samuel Evans presented a child about six years of age suffering apparently from hypertrophic cirrhosis of the liver. The family history is good and the personal history has the single significant element that the child was given a little beer when it was about two years old with its meals but never any other alcoholic liquor. The family are accustomed to take beer and wine freely at their meals. The first sign of illness was an enlarged abdomen with a wasting of the rest of the body. When the little patient came under treatment, though it looked pale, there was no anemia, that is, no deficiency of hemoglobin, or of number of red blood corpuscles. There has never been any jaundice present and there are no venous stigmata anywhere in the body. Urine is of high specific gravity and contains a little albumin. The stools have been regular with slight amounts of mucus occasionally. There has been no hemorrhage from the bowels. On percussion the liver is found to extend from the fifth interspace of the axillary line to three inches below the border of the ribs. The spleen is not palpable and has never been palpable even with the child in the knee-chest position. While the case contains some elements pointing to hypertrophic cirrhosis, there is an absence of the ordinary causes. Two cases have been reported in which patients though not taking alcohol drank coffee to excess. If, as has been recently thought, it is the gastro-intestinal disturbance produced by the alcohol, rather than the alcohol itself, which brings on the cirrhotic condition, it is possible that coffee producing similar disturbing symptoms, might have a like effect. In the present case coffee has been used very freely and there has been more than a suspicion that that was the causative agent. In answer to a question by Dr. James J. Walsh as to the employment of specific treatment in the case, Dr. Evans said that mercury had been used and improvement seemed to follow its use. The gastro-intestinal condition was better than before, there seemed to be less ascites and the child's limbs seemed to be gaining in flesh. The treatment consisted in small amounts of calomel given every day and the coffee has been given up completely.

Purpura Hemorrhagica.—Dr. Stowell described two cases of this disease recently under observation. The purple disease of the skin or the viscera is due to small hemorrhages in these organs and when the hemorrhages occur in the joints then it is spoken of as rheumatic purpura or Schönlein's disease. When there is blood in the stools it is spoken of as Henoch's disease. In Dr. Stowell's first case there was blood and mucus in the stools and some bloody vomit. There was considerable fetor of the breath, hemorrhagic spots occurred over the entire body. Medication seemed to have very little effect, though tannin, bismuth and the various astringents, as well as antiseptics were employed—all failed. In the second case the patient had green watery stools later streaked with blood. The temperature rose to 101.5° F., the pulse to 132 and the respirations to sixty. Pneumonia was suspected, but the fever fell to 97° F., after which the bloody stools stopped, but the purpura continued and death ensued. At the autopsy no dysenteric bacilli were found and there were no agglutinating properties demonstrable in the blood. The lungs were normal. Ecchymoses were found on the pericardium, in the mucous membrane of the cecum and intestines as well as in the liver.

Etiology of Henoch's Purpura.—A number of similar cases have been described by authors in Europe and America, but there is a great variety of opinion as to the cause of the disease. Some have attributed it to a lack of potassium salts in the blood; others to a lack of blood plaques. Henoch considered it a vasomotor disease. In recent times many have attributed it to a bacillary cause. At least one supposedly specific bacillary cause has been found in the blood. The blood usually shows the appearance of secondary anemia, but is often absolutely normal. This was the case in both of Dr. Stowell's patients. In a group of cases, a pig suffered from the disease and the owner, the swineherd, and a girl who took care of the animal, all contracted it. The disease is common in swine. The petechia in Dr. Stowell's cases were quite different from those hemorrhagic patches which occur in wasted children, especially when the skin is loose. Dr. Stowell has seen one of these cases not very long since where the baby was suffering from marasmus, although entirely breast-fed.

Dr. Henry Heiman, in discussing these cases, said that the blood is usually found normal in these cases. Hence the disease is probably due to a microbe, or even more likely to a deficient intima of the blood vessels.

Bronchopneumonia.—Dr. Bovaird said that at the Foundling 40 per cent. of the deaths are due to this, only two per cent. to lobar pneumonia. This does not give the absolute proportion, but it suggests the relative frequency. Children never die in the primary stage of simple congestion, but always in that of red or gray hepatization. At times a lobe is found only partly consolidated, a true lobular pneumonia. Often there is a heavy deposit on the pleura, sometimes greenish in color, plastered over the lung. At times small abscesses may be found. In bronchopneumonia, the lung shows a red, shiny section, not granular, as in lobar pneumonia. The bronchi project above the surface and pus may be pressed out of them. The appearance is often mottled or dappled dark gray with cellate trefoil or clover-leaf figures Empyema is more frequent than is thought. The bacteriology of lobar pneumonia is well established. In 95 per cent. of the cases it is due to the pneumococcus. It is now known that the pneumococcus of pneumonia is also in the circulation. The Klemperer's, twenty years ago, could not find the bacilli in the blood. Later Aufrecht found it in 20 per cent. of the cases. Now bacteriologists find them in practically all the cases. Hence the disease is a general infection with a localized lesion. Bronchopneumonia is due to a mixed infection, the commonest causes being the streptococcus or the bacillus of Friedlander.

Diagnosis of Pneumonia.—Dr. William P. Northrup said that the most important element in the diagnosis of pneumonia is its early recognition. What then are the signs by which an experienced matron in a children's hospital suspects the beginning of pneumonia? Not infrequently, at the Foundling Asylum, the matron will go up to a nodding child and put it to bed saying that it probably has pneumonia, when the ordinary physical examination will show as yet no signs in the lungs. As a rule the child with developing pneumonia first refuses breakfast. Sometimes it vomits then it ceases to play and at times becomes bluish. The onset is rather abrupt and there is a dopy, chilly, shivery appearance about the child. When examined it proves to be hyperesthetic and shrinks from the stethoscope. The fever in these cases will sometimes be found as high as 104° F. at the very beginning. The ordinary pulse respiration ratio is 1 to 4. When this is disturbed the physician should always look for an affection of the lungs. An increase of respirations to 40 with a pulse of 140 nearly always means pneumonia. The first physical sign that is noted is a shower of râles. Then there is diminished respiration and diminution of the bronchial sounds, both voice and breathing. Cough is inconstant and is of little value, bing dependent on the catarrhal condition of the upper air passages. Dulness is the last sign that occurs. The child is usually lethargic and somnolent owing to the toxemia. Not infrequently there is a little stiffness of the neck and arms in children suffering from pneumonia, owing to the fact that the muscles surrounding the thorax are put at rest by nature. This may make it a little difficult to differentiate from tuberculous meningitis, but the facial expression is very different in the two diseases. Tuberculous meningitis has an expressionless mask, pneumonia gives a drawn face. The important differential sign, however, is the disturbance of the pulse, respiration ratio. As a rule, nurses do not take the respirations of the patients under two years of age. This is important, however, and they should be instructed to do so. At times a central pneumonia may give no physical signs, and the only method of making the diagnosis will be from the appearance of the patient and the disturbance of the pulse respiration ratio. Not infrequently diagnoses made from this symptom alone are confirmed by a frank crisis followed by satisfactory convalescence.

Treatment of Pneumonia.—Dr. J. W. Winters said that lobar pneumonia is practically never fatal in children and that the main element of any treatment must be surely to do no injury, or to disturb the patient. Whatever treatment is instituted must have due regard to the individual peculiarities of the patient. It is important that children suffering from pneumonia should be kept in a comfortable warm room, at a temperature of about 72° F. At the society for the Prevention of Cruelty to Children, where many cases have been under treatment, no deaths have occurred, but the question of an equable temperature is considered so important that a special night engineer is employed so that the temperature of the room shall not sink during the night. A cold skin leads to contraction of the cutaneous vessels, throws more work upon the heart, causes a congestion of the vesceral vessels and especially of the weakened vascular system of the diseased lung. It must not be forgotten that nearly 80 per cent. of the heat radiated from the human body passes directly from the sin. Ten per cent. more goes through this same tissue by evaporation. The control of the cutaneous vessels is extremely important, whenever there is any disturbance of temperature.

Contraction of Cutaneous Vessels.—Any contraction of the cutaneous vessels causes the internal temperature to rise. Exposure to cold or douching with cold water, far from bringing down the temperature, tends to increase it. There are many physicians, however, who seem to harbor the idea that temperature can be directly controlled by exposing a sick baby to cold. One night last winter, Dr. Winters was asked to see, in consultation, a child suffering from pneumonia and found the baby absolutely naked in a cold room, with the window open. The physician said that he had been absolutely unable to reduce the temperature which was about 106° F. Dr. Winters suggested wrapping it in flannel from head to foot, prescribed large doses of niter and a small dose of Dover's powder. The physician was to remain with the child during the night and improvement began at once, as soon as the condition of the skin allowed the patient to give off heat rather than accumulate it. Exposure, whether to cold air or to cold water, causes an intense disturbance of the nervous system. Whenever there is fever, nervous phenomena are likely to be marked in children, hence the

muscular agitation often seen in febrile conditions. The nervous reflex from a cold skin causes violent inspiration, bringing the accessory muscles of respiration into play and seriously disturbing the child. Usually the child respires by means of its abdominal muscles and there is no disturbing expansion of the thorax. In pneumonic conditions this natural condition should be encouraged, but cold applications have a directly opposite effect. Ice is used in the treatment of pneumonia in certain institutions for children, but this remedy certainly could not be employed in private practice among intelligent people and, as a matter of fact, it is unwarranted, since there is no good reason for it. Without any use of cold or cold applications the pneumonias at the rooms of the Society for the Prevention of Cruelty to Children constantly improve and the mortality is nil. Dr. Winters considers that Dover's powder is an important remedy in the treatment of pneumonia, especially at the beginning, when there are irritability and unrest. The true Dover's powder, however, should be employed and not that made according to the modern formula, which druggists usually supply. As Dr. Dover originally wrote the prescription it should contain opium, ipecac and sulphate of potash. For the sulphate of potash sugar of milk has been substituted in recent years, to the great detriment of the effectiveness of the remedy. Sulphate of potash is diaphoretic. The new form of Dover's powder induces constipation and brings on nausea. As is well known, any disturbance of the gastro-intestinal tract in children suffering from pneumonia, may easily prove serious since abdominal conditions so readily interfere with respiration. Modern Dover's powder does harm rather than good. Dr. Winters does not think that any of the coal-tar products should be used. When an antipyretic is needed, aconite to its physiological effect is the best drug and has no bad after-effects and produces no complications because of special idiosyncrasies. It should be given as the conditions indicate. During the fever of pneumonia, children are often very thirsty. In order to quench their thirst, they will take milk even though they may have no craving for food at all. If more milk is given than can be readily digested it produces abdominal distress and gives rise to gastro-intestinal fermentation and consequently interferes with respiration. This is the most serious thing that could possibly happen in a pneumonia case, since it is well known that any meteorism soon interferes with regular respiration and makes the outlook serious. The child should always be given all the water that it can drink, but should not be tempted much with milk until sure that the thirst has been relieved. The tongue is the most important factor in estimating the condition of the patient. A good clear tongue means easy descent of the diaphragm.

Alcohol and Other Drugs.—Alcohol is almost never needed in lobar pneumonia. In feeble children with irregular pulse, especially about the time of the crisis it may be of assistance. It must not be forgotten that pneumonia does not end by crisis near so frequently in children as it does in adults. When alcohol is employed it should be given by the rectum, sufficiently diluted with hot water as not to produce any irritation When given by the mouth it often induces vomiting and is a frequent source of gastro-intestinal irritation. Strychnine should not be employed on general principles, but should be given for special indications about the time of the crisis. It should be given nearly always hypodermically. As a rule, no drugs should be given by the mouth. In septic conditions oxygen should be employed freely and the little patient's condition should not be allowed to sink too low before it is used. Properly employed, it is equal in value to whisky and strychnine.

Insidiousness of Pneumonia.—Dr. Rowland G. Freeman said that the diminution of the respiratory murmur is a valuable early sign of pneumonia and changes in this during the course of the disease show the development of pleural exudate or beginning empyema. Often there are no definite physical signs of a pneumonia and throughout the course of the disease there is apparently only a bronchitis. Sometimes the existence of a respiratory grunt is the only thing beyond the symptoms of bronchitis. It is only as the temperature comes down that the pneumonia consolidation makes its appearance at the surface of the lung and gives physical signs. It is probable that many cases of pneumonia are missed. Strychnine is well borne by children as a rule and should be employed in considerable doses. The use of alcohol would better be put off until near the crisis.

Nitroglycerin and Digitalis.—For cold extremities there is no better remedy than nitroglycerin. Digitalis is very valuable in conditions of heart disturbance but it produces so much irritation of the stomach, that it is often of doubtful service.

Dr. Charles G. Kerley said that the most important element in the treatment of children suffering from pneumonia is rest. Mother and nurse are directed that the child must be left in its crib, not taken in the arms, or held on the lap. The room must be kept at a temperature of 70° F., and once a day, usually about four in the afternoon, the child must be transferred to another room and the ordinary sick-room kept open for an hour in order to be well aired. Needless to say, the child must not be brought back to a cold room. The temperature must have reached 70° F. again before the child is returned. The air is important, so that a window must always be kept open, though the current of air must be so guarded as not to chill the room. The child must be warmly dressed, but protective dressing on the heart, such as oiled silk, only makes the child uncomfortable and irritable and hampers thoracic movement and consequently respiration.

Hygienic Measures.—The food must be reduced and, while the child is given plenty to drink, it must not be tempted to eat. A standing order is given that the child shall have an enema every twenty-four hours if there is no stool. The feet must be kept good and warm to make the circulation easier. No special drug is of any benefit and unnecessary drugging may easily do harm. Drugs must be given only when indicated. This holds good for strophanthus and strychnine and other stimulants as well as for less defensible remedies, for they must not be given on general principles. Digitalis is all right in theory, but it always disturbs the stomach. The gastro-intestinal tract must be kept in good condition at all hazards, for any irritation here causes interference with the action of the diaphragm and disturbs respiration. When the child's temperature runs high and the little patient becomes very restless, then a cold pack is the best possibly remedy. The arms and legs should be left free, but the child's thorax, should be wrapped in a large bath towel. In this Dr. Kerley takes direct issue with Dr. Winters, though he does not consider that the child should be shocked, or that it should be wrapped entirely in cold cloths. To cover the child entirely with a cold water bandage is surely to do harm. The pack may be put on at 90° F. and gradually the temperature of the water which is poured on the towel, may be reduced. As soon as the temperature reaches 101° F. the pack must be removed and then reapplied if necessary. There is no

special temperature for all patients. In some 90 degrees is suitable in others 50. In bronchopneumonia the same indications hold, though in this affection it is important to watch the gastro-intestinal tract, as the child may be ill for weeks at a time.

Bronchopneumonia.—In slow running bronchopneumonia counter-irritation is often of very great service. A poultice consisting of mustard one part and flour two parts, may be applied and kept on for from ten to fifteen minutes, or until the skin is reddened. Individual patients differ in their susceptibility to the influence of mustard, so no hard and fast rule can be given. This may be reapplied in from four to six hours, if necessary. There is an easiness of breathing and a softness of the cough that follows this treatment. Steam inhalations are also of value and if a little creosote is added to the steam it has an excellent effect. Twenty drops of creosote should be dropped in a quart of water and the child placed in a tent, allowed to breathe this for half an hour at a time, or, in severe cases, even an hour or an hour and a half. Oxygen is of great service when dyspnea is marked but the inhalation of the gas should not be continuous, as its intermittent inhalations for two or three minutes with two or three minutes of rest seem to do much more good.

Individuality of Treatment.—Pneumonia is a self-limited general infection, the complications of which cannot be prevented, nor the course shortened. The indication then is for supporting treatment. There is no per se treatment of pneumonia, but each little patient must be carefully studied. Cold is undoubtedly detrimental. The rules for the treatment of fever in adults do not hold in children. Some children stand the temperature of 104° F. very well. The physician's mainstay in the treatment of fever must by hydrotherapy. The coaltar products should be tabooed. Quinine is at times of excellent service, quiets the patients and gives sleep. Water must not be used cold in the treatment of children, for they do not react well and are disquieted thereby. Patients should be rubbed with lukewarm water, first gradually reduced in temperature, followed by a certain amount of alcohol. The idea is not to reduce the temperature, but to stimulate the heart and kidneys and the internal circulation and to soothe the nervous system. The temperature must not be knocked out or the patient will also be knocked out. As a rule, very few drugs are needed in lobar pneumonia and the fewer that are used the better. Inhalations, in Dr. Koplik's experience, have never done good, since they exclude fresh air and seem to cause cough. Moisture seems to have a like effect. Poultices should not be used as they weigh down the chest. In cases of accumulation of pleuritic fluid, puncture to remove it is inadvisable, unless absolutely necessary. The struggle and excitement incident to even such a slight operative procedure always do more harm than good.

Dr. Stowell said that steam inhalations in his practice have always seemed beneficial. In the three classes of patients that have come under his care, children in hospitals, in the tenements and in the homes of the well-to-do, though treatment has been very differently applied, in its faithfulness the results have been nearly the same. In the hospital the doctor's directions are absolutely followed, in the tenements they do what they can, in the homes of the wealthy they do what they please. The mortality in all cases is about the same. This is evidently an argument in favor of simplicity of treatment.

Absence of Cough.—Dr. Walter Lester Carr said that cough is usually wanting in children suffering from pneumonia. Though there is often an expiratory effort which the nurse may call a tickling. In most cases of pneumonia among the children the complication that occurs is gastro-intestinal more than cerebral and the possibility of mistake in diagnosis on this account must be remembered. Cold is badly borne by children and there must of course be no question of the plunge bath, no matter how high the temperature. Lobar pneumonia causes very little necessity for drugs, but bronchopneumonia requires the greatest of care to meet the indications of the individual case.

Steam Inhalations at the Babies' Hospital.—Dr. Kerley said that in the new Babies' Hospital a special room for steam inhalations, the steam being supplied from the heating apparatus, has been constructed. It is considered of the greatest possible service, indeed almost indispensable in the treatment of bronchopneumonia and bronchitis.

Dr. Dessault said that as pneumonia is a self-limited disease, the mortality is very low and the prognosis of cases can often be judged from the occurrence of albumin in the urine. The outlook is always unfavorable when albuminuria is present. Dr. Fenwick, of London, has applied this same idea to adults and finds it of very great value. The presence of even traces of albumin in the urine should put the attending physician on his guard and keep him from making any promise as to results.

At the annual election of officers, held at the close of the meeting, Dr. David Bovaird, Jr., was chosen as chairman and Dr. Matthias Nicoll, Jr., secretary of the Section for the ensuing year.

THE WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, held at Denver, Colo., December 28 and 29, 1903

The President, Alexander Hugh Ferguson, M.D., in the Chair.

Carcinoma of the Lung.—Dr. W. W. Grant, of Denver, Colo., read a paper on this subject in which he reported two cases, one of which recurred after an unusually long interval, and having at one time coincident tubercle bacilli, and occurring several years ago. The other was recent and seemingly primary.

Pancreatic Cyst.—Dr. Grant gave the clinical history of a case of pancreatic cyst. He spoke of the causes of pancreatic cyst, reviewed the literature of reported cases, which showed convincingly that the disease was essentially surgical, and that delay in operating was as dangerous and fatal as in appendicitis. The gengrenous cases could only be saved by promptly opening the abdomen and draining. Formerly and recently reported cases in the *Annals of Surgery*, by Woolsey, which seemed unfavorable for operation, amply attested this. The suggestion in the treatment of the sac was to dissect it out if small, but in the case of a large sac this attempt was manifestly unsafe and dangerous. The extensive adhesions made it exceedingly difficult, and extravasation of pancreatic juice or septic material would probably destroy the patient. Patients had died from this treatment; while to attach the sac to the abdominal peritoneum, if not already adherent, and drain, was safe, and undoubtedly the best treatment of a large cyst. Pancreatic disease often simulated intestinal obstruction, and the statement might be safely accepted that if the surgeon opened the abdomen and did not find obstruction or perforation of the stomach, but observed fat necrosis, the pancreas was, in all probability, the source of the trouble.

Dr. Grant said several writers had considered the differential diagnostic point mentioned by Dr. Harris, but when it was remembered that cases of pancreatic cyst were more frequent in very fat subjects, and that there was quite uniform distention of the intestines, the stomach not being so much distended because of the pressure of the tumor, or, if so, it was entirely out of its normal location, it was difficult, if not impossible, to isolate the transverse colon and the stomach. He had never succeeded in getting any benefit from artificial distention in other cases, although he did not try it in this case.

Accidental Perforations of the Uterus.—Dr. D. S. Fairchild, of Des Moines, Iowa, said that the use of the sound and the curette in gynecological practice was probably the most frequent cause of this accident in legitimate practice. The facility with which the sound could be used in exploring the interior of the uterus and in repositing a retrodisplaced organ was no doubt responsible for some of these accidents. The curette, however, was often used in an indiscriminate manner and as a routine treatment in a great variety of uterine difficulties that could be better treated by other means with a greater prospect of permanent results. He mentioned a case that came under his observation this year which illustrated the ease with which a perforation of an apparently healthy uterine wall could be accomplished, and what was needed in cases of this kind.

Dr. W. L. Bullard, of Pawnee City, Neb., mentioned two cases of perforation of the uterus, one of which was produced by a crochet hook of the ordinary size. An attempt was made to find the hook, but without avail. The patient was left alone. Six months after this she became pregnant, and the crochet hook was discharged through the anterior abdominal wall. Two months later the product of conception was expelled in the natural way.

Treatment of Gastric Ulcer.—Dr. H. D. Niles, of Salt Lake City, Utah, in a paper on this subject, presented the following conclusions: (1) Post-mortem statistics, clinical experience, and recent operating-room observations all tend to confirm the belief that neither the frequency nor the grave importance of gastric ulcer is fully appreciated by the profession generally, and the majority of cases are not recognized as such in life. (2) An earlier and more positive diagnosis means greater alertness in our observation and interpretation of symptoms, and more frequent exploratory operations. (3) In the history of every benign or malignant ulceration situated in a safely accessible region, there is always a time when the pathology can be corrected or favorably modified by appropriate mechanical means. (4) Up to the present time the recognized indications for operative procedures in gastric ulcer have been the symptoms produced by the remote resultant pathology, as hemorrhage, perforation, pyloric obstruction, cancer, etc., but our aim in the future should be to make an earlier diagnosis and by the timely application of a rational treatment prevent the occurrence of these later and more serious manifestations of ulcer. (5) Taking into stricter account the local etiological factors will undoubtedly aid us in the prevention, diagnosis and treatment of gastric ulcer. (6) The causative pathology deserves more consideration in the surgical treatment of gastric ulcer than it has yet received. (7) Perforation always demands the promptest surgical interference. (8) Hemorrhage from gastric ulcer is best treated by gastro-jejunostomy. (9) Open or cicatrized ulcers near the pylorus always indicate rest for the parts and a sufficient outlet for the stomach contents. (10) A posterior gastro-jejunostomy with sutures accomplishes these objects with the minimum risk and the most satisfactory results, and hence should usually be the operation of choice. (11) Our future advancement in the treatment of gastric ulcer must come from an earlier recognition and better understanding of the antecedent coexisting and resultant pathological processes rather than from any further refinements in operative procedures.

Etiology, Symptomatology and Diagnosis of Gastric Ulcer.—Dr. Frank C. Davis, of Des Moines, Iowa, said that clinically the simple ulcer was not so frequent as the statistics of post-mortem examinations would lead one to expect, being from six per cent., as diagnosed by Lebert, to .82 per cent. as observed by Fenwick. In the extensive records collected by Welch, ulcers cicatrized or open was in about five per cent. of persons dying from all causes. Fenwick, from the examination of nearly 48,000 post-mortem records, found scars or ulcers in 4.2 per cent., and in 20,000 autopsies of persons dying from various causes, open ulcer in 1.5 per cent. If one took even the lowest percentage as found post-mortem, namely, 1.5 per cent., it would be seen that every other case was undiagnosed in life. Clinically and pathologically the author classified gastric ulcer as acute, acute secondary, and chronic. Each classification was expatiated upon. Hematemesis was a sign of such unmistakable value that one only needed to exclude a few other sources for the blood to establish a diagnosis by it alone. The symptoms of acute and chronic ulcer were detailed. A conservative estimate of perforation placed it at about 5 per cent. It occurred most frequently in females, which might be accounted for by the fact that many more women suffered from the acute ulcer, and that the chronic ulcer developing from the acute was more liable to perforation. The accident might occur suddenly or be preceded by an increase of pain and vomiting, or by a vomiting of blood.

Perforating Gastric Ulcer.—Dr. Archibald MacLaren, of St. Paul, Minn., said that perforating gastric ulcer was fully as common as extrauterine gestation, and that when the eyes of physicians were opened to this fact, they would be able to see them, diagnose them early, and save many lives that were now lost. In this country he did not believe that the perforation cases reached the hospitals as often as they did abroad. His experience left him to believe that Dr. Richard Harte was correct when he said that rigidity or tension of the abdominal muscles was the keynote to the early recognition of peritoneal perforation from whatever source. The pain might subside, the temperature might not be elevated, but the rigidity continued even up to the end. He believed that many cases could be correctly diagnosed, as was proven by a few cases which he reported, and by the many cases which were constantly being published in the journals.

Dr. Charles W. Oviatt, of Oshkosh, Wis., mentioned the case of a man, sixty-two years of age, a laborer, who had never complained of any symptoms of gastric ulcer. He had eaten a hearty meal, laid down on the lounge feeling perfectly well shortly after, but within an hour he rolled over to the floor with agonizing pain. A physician was called, who gave large doses of morphine hypodermically, without any benefit, and the patient died within a few hours. Post-mortem examination revealed a perforating ulcer in the posterior wall of the stomach which seemingly had attempted to heal. There was no blood in the stomach but the abdominal cavity was filled with stomach contents.

Dr. Charles H. Mayo, of Rochester, Minn., said that after examining 1,100 stomachs by test meals, laboratory testing and physical examination, anemia was a very important factor; next, long-continued neuras-

thenic symptoms. He mentioned one authority who, in examining 2,200 cases at autopsy, found that twenty per cent. of women showed signs of ulcer of the stomach, and only 1½ per cent. of men. Welch, in an examination of eight hundred cases of gastric ulcer, found 60 per cent. in women, and 40 per cent. in men. The speaker and his brother had operated on approximately 400 cases, and of 1,500 cases of stomachs examined, they had found that the proportion was about the same as that given by Welch. Welch also found in an examination of 788 cases of ulcer of the stomach that only 28 occurred in the greater curvature, so that the greater proportion of them were fund in the pyloric end of the stomach. Of cases of cancer of the stomach, Dr. Mayo had elicited a history of chronic ulcer covering a period of from one to fifteen years. His statistics showed 88 per cent. of gastric ulcer, and 12 per cent. of duodenal ulcer. The tendency was more and more to class the first two and a half inches of the duodenum as a part of the stomach. In 31 cases of acute perforation of the stomach and duodenum, 11 occurred in the duodenum in this first 2½ inches, and he had operated on 26 cases of ulcer of the duodenum.

Dr. M. L. Harris, of Chicago, said the extensive experimental work of Futterer showed it was impossible to produce gastric ulcer in an animal until the hemoglobin of the blood had been reduced below a certain point; that all lesions of the mucosa produced in healthy animals readily healed. When the hemoglobin was reduced below a certain point, producing a marked anemia, then these lesions developed into typical ulcers. These observations showed the importance of an examination of the blood in these cases. Another point was the examination of the feces for hematin crystals, as a means of diagnosis in obscure cases of gastric ulcer.

Treatment of Hematemesis by Gastro-enterostomy with Report of a Case.—In a paper on this subject, the author, Dr. F. Gregory Connell, of Leadville, Colo., classified the operative treatment of hematemesis into direct and indirect. Under direct he included (1) excision of the ulcer; (2) partial gastrectomy or pyloroplasty; (3) ligation of the principal artery; (4) cauterization or curettage of the ulcer; (5) ligation of the mucous membrane, and (6) ligation of all coats. Under the indirect he mentioned (1) gastro-enterostomy; (2) pyloraplasty; and (3) gastrotomy. After considering the direct method as a whole, he stated that these were not in common use, because of such objectionable features as the difficulty of locating the ulcer, the fact that the lesion was frequently multiple, the presence of firm and complicating adhesions, and the indistinct limitations of the pathological tissue. The high mortality rate of some and the impracticability and unreliability of others had been the cause of a general turning to the indirect method, as exemplified by gastro-enterostomy. The manner in which a gastro-enterostomy allowed an ulcer to heal was well understood and practically settled, but as to this same operation acting as a hemostatic measure, no such substantial reasons as those advanced for the healing could be presented. While rest and drainage undoubtedly favored clotting and the cessation of hemorrhage from small blood vessels, it was difficult to understand how they could arrest hemorrhage from a large artery with a lateral opening, as in the case reported. As one was unable to determine with any degree of accuracy the nature or the source of the hemorrhage, gastro-enterostomy was indicated only after a thorough search for the bleeding point. The exact status of gastro-enterostomy in hematemesis was not well defined, as was shown by numerous quotations. It had been said that a search for the bleeding point was futile, harmful and unnecessary, and that a gastro-enterostomy would without doubt prevent recurrence of the hemorrhage. To show that gastro-enterostomy would, without doubt, prevent recurrence of the hemorrhage, the author reported one case and cited others from the literature. Gastro-enterostomy was indicated in hematemesis (1) after a thorough search had failed to reveal the source of the hemorrhage. (2) Where the source of the bleeding was discovered, but in such condition as to make direct treatment impracticable or impossible. The conclusion, based upon a sad experience and a review of the literature, was an endeavor on part of the author to discountenance the idea, which had become quite prevalent, that nothing was to be gained by searching for the bleeding point, as gastro-enterostomy was all that would be necessary to prevent recurrence of the hemorrhage.

Two Cases of Acute Hematemesis in which Gastro-enterostomy was Performed.—Dr. Leonard Freeman, of Denver, Colo., detailed a case in which he performed a posterior gastro-enterostomy. A Murphy button was employed, having the end within the stomach smaller than that within the bowel. The stomach contained bloody fluid. Recovery was uninterrupted. The button was passed on the twenty-third day. There was no further hemorrhage. About seven months later this patient suddenly died from hematemesis, the hemorrhage having begun about three months after the operation, small quantities of blood being frequently vomited subsequently. In Case II. a posterior gastro-enterostomy was done, and a Murphy button used, the ends of which were of unequal size. The stomach showed no external sign of ulcer, and no internal exploration was attempted. The organ was markedly dilated with gas and fluid. Reaction from the operation was so satisfactory that hopes of recovery were entertained; but in spite of no recurrence of the hemorrhage, death occurred at the end of fifty hours, due apparently to the great loss of blood. Autopsy revealed an ulcer as large as a watermelon seed on the posterior wall, at the junction of the lower with the upper two-thirds of the stomach. A small atheromatous artery, plugged by a thrombus, could be seen in the floor of the ulcer.

Dr. O. Beverly Campbell, of St. Joseph, Mo., said, in regard to the closure of the opening made in gastro-enterostomy by the suture method, he had performed 16 experiments on dogs. In 12 he used the Kocher method of suturing, and in all of them he did an anterior gastro-enterostomy. The opening in each instance was quite large. The dogs were reoperated at periods of from three to six months, and at the end of three months in six cases the opening was reduced to such an extent that the index finger could not be passed through it without a little force. In six of the cases there was almost total obliteration of the opening at the end of six months. In four there was a slight opening through which only a small probe could be passed. A vicious circle was established in 40 per cent. of the cases. These experiments showed a tendency, where there was no obstruction at the pylorus, for the opening to close, whether it was made with the Murphy button or by the suture method. A larger opening was obtained if the Connell suture or the Kocher suture was used, and in every case the speaker made a rather large opening. Six dogs, in which a vicious circle was established, began to fail in flesh at the end of about two months, and at the end of the third month they were opened and a vicious circle found. In every instance there was more or less narrowing of the opening.

Dr. Charles H. Mayo reported a case in which

gastro-enterostomy failed to arrest hemorrhage. During the past year he operated upon a man forty years of age, who gave a history extending over a few years of occasional stomach disturbance and vomiting of blood. By the laboratory test a little blood was found in the stomach. At the operation, in examining the stomach, he did not find any external evidence of the ulceration. The stomach was dilated. He did a gastro-enterostomy, but there was more hemorrhage after it than before, and the man died at the end of four days. He was very anemic at the time of operation. At the autopsy the intestines were found filled with blood. The gastro-enterostomy was a posterior one, after the Mikulicz method, and the line of suturing was perfect. There were no large ulcers in the stomach, but there were two or three points of erosion.

The Correction of Retrodisplacements of the Uterus.—Dr. Charles W. Oviatt, of Oshkosh, Wis., in a paper on this subject referred to the many operations devised for correcting uterine retrodisplacements. He stated that whatever the operation selected, it should permit of thorough intrapelvic work and should be one that restored the normal axis of the uterus, at the same time leaving it free to adapt itself to its normal range of motion. The operation he described as meeting these requirements was that devised by Dr. George H. Noble, of Atlanta, Ga. A description of the Noble operation could be found in medical literature. During the last year the author had made this operation 23 times. In all but three, there were intrapelvic or other complications. In ten, the appendix vermiformis was removed either because of a history of definite recurring attacks of appendicitis, or because from its appearance it was deemed wise to remove it. In one case a broad ligament cyst was removed, and in several diseased appendages were taken out. These were mentioned to show that there was no difficulty in doing any necessary intrapelvic work through the transverse incision and separation of the recti muscles. In all the cases, local office treatment by means of tampons or pessaries had been resorted to without relief. Most of the cases were in women who were obliged to work and who preferred to undergo an operation rather than submit to further treatment. The three uncomplicated cases were marked neurasthenics with dysmenorrhea. While the displacement remained corrected, there had as yet been no improvement in the dysmenorrhea, and little or none in their general condition. There were no deaths or serious complications following these operations. The advantages of the operation were: Through the one incision any pelvic complication might be treated. The operation utilized the strongest part of the round ligament instead of its distal end. The normal mobility of the uterus was not disturbed, and it was left in the pelvis where it belonged. It caused no bladder irritation and no dragging because the traction on the ligaments was in the direction of their natural course.

The Surgical Treatment of Goiter.—Dr. Charles H. Mayo, of Rochester, Minn., in discussing this subject, said that the respect American surgeons held as to the ability of Continental surgeons was to a considerable extent due to their statistics on goiter. To the peculiar formation of the capsule of the thyroid were due many of the symptoms occasioned by enlargement. Closely investigating the gland, it divided posteriorly and also enclosed the trachea, esophagus, and part of the pharynx. Accessory glands were not uncommon in the lines of inversion from the pharynx in the original formation of the organ. It was probable that the lymphatic system acted as its duct, and a study of the function of the lymphatics would explain some factors in the etiology of diseases of this body. In young people at the age of sexual activity, enchymatous goiters were quite common, but, as a rule, readily responded to treatment. Reverdin, in an analysis of 3,408 cases, placed the mortality from total extirpation at 19 per cent.; partial, 3½ per cent.; from intraglandular enucleation, at .78 per cent.; from resection, at 6.6 per cent. The writer's experience was derived from 108 operations upon thyroid tumors. Of these, there were 34 exophthalmic cases, with 6 deaths; 2 malignant, with 1 death; one large lingual thyroid. Two cases presented separated tumors of the pyramidal lobe. There were 71 cases of cystic, colloid, adenomatous and mixed types of goiter operated upon, with one death, from pneumonia, on the eighth day. The recurrent laryngeal was permanently injured once, and its function temporarily impaired several times. The Kocher collar incision was ordinarily used and a free exposure of the gland made. The overlying muscles were either tracted aside or severed, according to the case. If the capsule was thickened over the local tumor, or whole gland, the Socin method of enucleation was commonly employed. If the gland retained its general form, the largest lobe, usually the right, was extirpated, frequently leaving its posterior capsule to protect the laryngeal nerve. Ether anesthesia was usually employed. Occasionally cocaine was used locally, if there was much tracheal disturbance or severe exophthalmic symptoms. Chloroform was rarely given. All anesthetics were preceded by a hypodermic of morphine. Some thyroidism usually followed for one to three days.

Intestinal Perforation in Typhoid Fever.—Dr. Byron B. Davis, of Omaha, Neb., referred to the statistics of Taylor, Osler, Finney, Keen, and others, and said that even under the past dilatory tactics the results had been very gratifying. The first 24 operations for typhoid fever reported showed six recoveries, or 25 per cent. When it was considered that a very large number of the operations thus far reported for typhoid fever had not been done until general peritonitis had been fully established, 50 per cent. of recoveries did not seem unreasonable, if operation was done before the advent of the peritonitis. The latest statistics from Johns Hopkins gave 41 per cent. of recoveries. There they were striving to operate for the perforation merely, but several cases were recorded with a fully developed peritonitis. Another point affecting the mortality was that a small per cent. of the cases dying after operation did not die from the operation *per se* or the perforation, but as a result of the general typhoid infection. The author thought such cases should not be charged against the operation.

Dr. A. I. Bouffleur, of Chicago, referred to the differential diagnosis between perforation and hemorrhage. One case operated on by him was one in which there was a difference of opinion as to whether or not hemorrhage or perforation was present. This case occurred several years ago, before the value of a blood count was emhasized. Operation was performed, and the patient recovered. The case emphasized the point that even in cases of doubt as to whether there was perforation or marked hemorrhage, operation was not necessarily fraught with serious danger.

Surgical Treatment of Nephritis.—This was the title of the President's Address, delivered by Dr. Alexander Hugh Ferguson, of Chicago. Reference was made to the early history of this subject, and to the priority of the operation. The author added three cases to those he had already published of renal decapsulation and puncture for active diffuse nephritis. In looking over the literature, the author finds that the causes of death after the operation in 123 cases, by different surgeons, were as follows: Four died of pulmonary edema;

6 of uremia; 4 of coma; 3 of sudden heart failure; 3 of exhaustion, and 1 each of endocarditis, suppression of urine (ether being used), anuria, general dropsy, collapse, pleuritic effusion, and myocardial thrombosis. There were 27 deaths out of 123 cases within a year after the operation. A closer analysis shows that of these 27 deaths, 6 died within 18 hours after the operation; 9 between one and nineteen days; 2 between two and seven weeks; 3 between two and three months, and 1 lived a year. The vast majority of these deaths should not be attributed to the operation. Even allowing all deaths within a week to be due to the operation, there would be a mortality of only about nine per cent. When the limitations of the operation were more clearly defined, and many of the extreme cases left alone, the author thought the mortality should not be more than five per cent. in the hands of experienced surgeons. It was fair to conclude that the earlier an operation was performed in these cases, the less would be the fatality, and the greater the benefits.

(To be Continued.)

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Stated Meeting, held January 4, 1904.

Effect of Altitude on Blood Corpuscles and Blood Plates.—Dr. G. T. Kemp, of the University of Illinois, read this paper, in which the conclusions reached during a trip to Colorado for the study of the blood were reported. Observations on the blood of six healthy individuals were made at varying altitudes on the plains, at Cripple Creek and on the summit of Pike's Peak. The well-established fact, known since the time of Behr and Biot, that rise in altitude causes an increase in the red blood corpuscles, was illustrated in the counts made on this expedition, but at the summit of Pike's Peak, in addition to this text-book increase, a marked variation between the morning and afternoon count was noted. Early in the day the red blood corpuscles were much higher than later and in one case this difference, which was always over 500,000, amounted to 1,000,000. In a general way the hemoglobin curve followed that of the reds, but not exactly; and the variations of the hemoglobin were less marked than in the corpuscles. For this reason when the corpuscles were markedly diminished in number each one was carrying a high percentage of hemoglobin. The ratio of the blood plates to the reds (normally 1 to 15) was fairly high in Illinois. At Cripple Creek an enormous fall took place, signifying of course a marked increase in the number of plates. This fall which continued during the stay in a high altitude was more marked, more regular and of longer duration than the changes in corpuscles or hemoglobin. This fact would seem to point to a new and safe and more constant indication as to the blood condition in the ratio of plates to corpuscles. As to the nature of blood plates Dr. Kemp's work tends to favor Hayem's theory —that they are hematoblastic; for after the increase in plates had continued for a while hemoglobin was found in them both by ocular and chemical tests. By artificial gastric digestion Dr. Kemp found that the platelets are rich in nuclear matter relatively to the corpuscles. The leucocytes were not affected by the altitude and it looks as if the blood plates had some genetic relation with the reds but not with the whites. In counting the plates an extremely small amount of blood must be drawn and a drop of methyl green (containing some formaldehyde for fixing purposes) placed over it. The count should be made with a one-twelfth oil lens.

Dr. Welch, in the discussion, said that in disease the platelets vary greatly in number, so that in any case one has to know the normal for that individual to draw any inference as to the number of red blood corpuscles. "Platelets" is not an exact term. He agrees with Arnold, who lays some stress on the granular material of the blood.

Dr. Osler remarked that large numbers of blood plates are seen clinically in two classes of patients; first, in the new-born, and second, in every case of marked cachexia. They are not, however, present in large numbers in cases where there are evidences of blood regeneration. He has never seen a platelet containing hemoglobin, the only point about which he is sure, being that, whatever their origin, the blood platelets are a definite morphological element of the blood.

Vaccine and Vaccination.—Dr. Dock, of Ann Arbor, Mich., read this paper. No method for the determination of the dose for vaccine has ever been devised. We measure it roughly by the lesion produced or by the degree of immunity conferred, but the existence of normal immunity makes the latter method quite inexact. In the early days the so-called lymph was obtained from spontaneous cowpox. Next humanized virus was used, being passed from arm to arm (in one case for forty-four years). But it was found that the lymph eventually died out and so cowpox or accidental horsepox was used as its source. Later retrovaccination was done with the idea of increasing the virulency by changing the medium. In the next few years humanized serum was used, but the transference of syphilis told against this method. In the early days the lymph was dried between glass plates, on linen threads, glass stoppers, quills, lancets and even thorns. Capillary tubes were also used early in the history of vaccination. The lymph has been applied in various ways—by actual incision, by hypodermic injection and by forcing it under a blister artificially produced. The vaccine pulp contains (beside the liquid) leucocytes, fat, specific and accidental germs; but in spite of the objections to it it is always used in Germany where vaccination is thorough and successfully done. In the preparation of vaccine, young calves—usually females—are used. After previous washing and inspection linear scarifications are made (usually on the abdomen), with aseptic precautions. The seed virus, either of cow or human pox, is then smeared on. In a few days the vesicles form, the skin is again washed and pulp is collected by scraping with a curette. The lymph was formerly mixed with various antiseptics, but now nothing but glycerin is used. In the United States there is absolutely no control over vaccine manufacture, and Rosenau showed that much of the lymph in circulation is badly contaminated. As to the method of vaccination, the scab should not be too large, nor should it be too superficial. In Germany an incision is used entirely, and this method is a very good one. Glycerinized lymph gives a small bacterial content with good specific properties.

Dr. Welch, in the discussion, said that tetanus has undoubtedly been carried by vaccine lymph, for the inoculation experiments to the contrary are by no means satisfactory. Certainly inflammatory conditions are so carried and this fact is a national disgrace. A board of health having control of vaccine manufacture throughout the country is badly needed.

Stated Meeting, held Monday, January 18, 1904.

Results of Some Recent Experiments on Blood Pressure.—Dr. Erlanger read this paper. The pressure usually estimated is the maximum pressure, but the difference between this and the minimum pressure (a quantity which Dr. Erlanger calls the pulse pres-

sure) is, he has found the most important thing to determine. It measures the velocity of the blood flow, corresponds to the mean blood pressure and is nearer the minimum than the maximum. It was found that in the apparatus usually used to measure blood pressure the variations in the size of cuff lead to inaccuracy in the results; for by determining the intra-arterial pressure (which is, of course, the true blood pressure), the readings when a narrow cuff was used were found to be always too high. By placing the cuff on the bared artery this elasticity error was found to be in the tissue, and it was shown that when we determine blood pressure clinically in the brachial artery we practically measure it in the aorta. A case of postural albuminuria was studied with reference to arterial pressure, and it was found that with the patient recumbent the pressure was lowest, that it rose on standing and fell again on sitting. The maximum pressure, however, showed practically no changes with the posture. The pulse rate varied inversely with the pulse pressure, but the volume of the arm used in the determination varied directly with the pressure. The albuminuria disappeared when the patient sat or lay down, but was present when he stood, and the angle at which it appeared was found to be 30°, the place at which pressure changes were first noticed. It was found that increased pulse pressure gave a diminution in the urine output with an increase of the solids and the nitrogen. Albumin in the urine means a lowered vitality of the renal epithelium, but these experiments suggest that the circulatory changes may be the primary factor. The pulse pressure and not the maximum pressure, which is the quantity usually estimated, is the important feature in blood-pressure work. Dr. Futcher referred to a recent case of cyclic albuminuria in which a fairly large albumin content with a high blood pressure changed, by means of rest in bed, to a trace of albumin and a pressure of 112 mm. of mercury.

Mental Symptoms Connected with Distinct Visceral Changes.—Dr. Carey Gamble reviewed Dr. Head's recent paper. Head divides the symptoms into hallucinations, moods of depression, etc., suspicions, loss of memory and attention and active insanity. Dr. Gamble reported several cases which seemed to agree with Dr. Head's theory that insanity is nothing more than mental wrongness and due to visceral changes. The first was a case of mitral stenosis with hallucinations of sight occurring in the morning, and after attacks of pain. In another patient asthma was associated with olfactory disturbances in which coffee gave the sensation of H_2S. Another showed auditory delusions with periods of depression. In this case the visceral changes were adherent pericarditis. Two of the cases with stenotic lesion of the mitral valve expressed their mental changes in periods of depression and exaltation and moods of suspicion. In one patient associated with asthma and emphysema there was a loss of attention and memory and great unreasoning fear. Depression with arteriosclerosis and hallucinations with aortic insufficiency were the other two cases in the series.

Dr. Paton called attention to the fact that the mental symptoms following acute diseases may be either the ordinary neurasthenic conditions, which are stable in character, or the so-called psychasthenic conditions; and we know of no explanation why they should assume one character rather than the other.

Periureteral Arterial Plexus.—Dr. Sampson read a paper on this subject. His attention had been called to this anatomical feature by the importance of the ureters in operations for carcinoma of the cervix. The plexus is supplied by the ovarian, renal, uterine, vaginal and iliac arteries and also gets direct branches from the aorta. The anastomosis is free and any vessel in the plexus may be injected from any other. Dr. Sampson found that when the smaller branches which are intimately connected with the ureters were stripped off and slight damage done to the ureter necrosis occurred. Clinically the ovarian, internal iliac and uterine arteries have been tied with the idea of reducing the blood supply of malignant growth and no necrosis has followed. This is, of course, easily explained by the part which the renal artery takes in the formation of the periureteral plexus. The pelvic portion of the ureter is inclosd in a fibrous sheath and one must, in operating on a carcinomatous uterus, guard against any interference with the periureteral plexus and any undue insult to the fibrous sheath in which it runs.

ORIGINAL ARTICLES.

THE ECONOMIC VALUE OF MEDICAL SCIENCE.*

BY W. GILMAN THOMPSON, M.D.,

OF NEW YORK;

PROFESSOR OF MEDICINE IN THE CORNELL UNIVERSITY MEDICAL COLLEGE IN NEW YORK CITY.

UPON this the occasion of the fifty-sixth anniversary of its foundation, the New York Academy of Medicine has every reason for congratulation upon its material success and for just pride in the honored position which it has won among the highest public institutions of the city. Comfortably housed in a well-appointed home, it has gathered in its library the medical lore of every country and every age, a collection widely famous for completeness, as it is for admirable arrangement and convenience of access. In its rooms may be met the expounders of the best medical thought of the day, and generous alike to members and non-members, the Academy extends its privileges to other societies and welcomes the stranger within its gates. Such a truly democratic institution, always free from the domination of any particular sect, vigorous, self-supporting, accessible alike to young and old in the profession, and as eager to work for the service of the community as to benefit its own members, cannot fail to command a high degree of public respect and confidence. It is this ever-broadening relationship of medical science to large public interests which forms the theme of discourse this evening, with special reference to "The Economic Value of Medical Science."

Unquestionably the most far-reaching economic benefit derived in recent years from medical science lies in the fact that the public are being taught not to flee from epidemics and pandemics, but remain to intelligently combat them. The wild stampede of whole communities, the shotgun quarantine with all its horrors, the utter paralyzation of all commercial interests in the face of an epidemic threatening from a foreign shore, are conditions forever past and replaced by measures so mild in contrast that they would be almost ludicrous in their simplicity, were they not so powerful in their effects. Thus, in many instances, instead of indefinitely quarantining the patient and destroying all his personal property, we quarantine the mosquito, destroy the rat, or boil the water in which we have learned to recognize the source of danger.

During the 100 years from 1798 to 1898 more than 80,000 deaths from yellow fever were reported in this country. J. F. Rhodes, in his "History of the United States" (Vol. IV) writes that as late as 1853 the mortality from yellow fever in the localities in which it prevailed, rivaled that of the Great Plague in London. In New Orleans, in an epidemic which lasted for three months: "It was impossible to bury the dead. Men went about in carts knocking at every door, and crying out, 'Who have dead to bury?'"—How inconceivable such a condition appears today, after a period of only fifty years! At a still earlier time such epidemics prevailed as far north as Philadelphia and New York. John Bach McMaster writes in his "History of the People of the United States" (Vol. I, pp. 30, 31): "Every few years during the dog-days the yellow fever raged with more violence in the Northern cities than it has ever done in this generation in the cities of the Far South. Whole streets were depopulated. Every night the dead-cart shot its scores of corpses into the pits of the Potter's field."

The mode of propagation of the bubonic plague is now understood and in India it is claimed that the use of Haffkine's serum reduces the susceptibility among those exposed to this infection 75 per cent., and the mortality of those attacked is reduced by 90 per cent. The cases of plague which reached Glasgow in 1900 were so successfully dealt with that the advent of a disease which formerly would have completely inhibited the commerce of a great port, produced no more than passing mention in the public press; and the few cases which have appeared in San Francisco and the quarantine station of New York in recent years have created no undue alarm. It is a hope, fully capable of realization, that soon the plague may be confined permanently to its home in the valley of the Euphrates, as cholera bids fair to be restricted to the valley of the Ganges, and even there these scourges may yet be vanquished, if they can be deprived of their only allies, ignorance and prejudice. Typhus fever and leprosy have been practically exterminated from many countries which were formerly ravaged by them in disastrous epidemics. Malaria is now to be reckoned as a preventable disease, capable in time of extermination from any community. It is easy to estimate the cost of this disease in a given locality and demonstrate the financial saving which would accrue from its extinction. Ricchi ("Malaria According to New Researches") states that the Adriatic Railroad Company, employing more than 6,000 men, loses over 1,000,000 francs a year from incapacity of its laborers caused by malaria. Angelo Celli (in "Malaria According to the New Researches") estimates the mean annual mortality in Italy from malaria at 15,000. There are besides 2,000,000 cases of the disease per annum, and 5,000,000 acres of land are rendered unfit for cultivation through this scourge.

* Anniversary Discourse, delivered at the New York Academy of Medicine, November 19, 1903.

Local epidemics of infectious disease, as well as infant mortality, are being markedly lowered wherever medical science has been intelligently applied and the mortality in large cities throughout the world is undergoing constant reduction. In New York City, for example, a century ago the annual death-rate was fully 30, and probably much higher, if allowance be made for the imperfect statistical records of the period. To-day it has been reduced below 18.5, despite the conditions of overcrowding and pauper immigration which characterize the modern development of the city. In the early days of the past century a large proportion of persons above twenty years of age were deeply pitted by smallpox, yet how rarely one meets a face so disfigured to-day!

Interesting computations have been made regarding the financial cost to the community of tuberculosis. Among such calculations is one published in a recent circular of the Imperial German Health Bureau, which is as follows: About 90,000 persons between fifteen and sixty years of age die yearly from tuberculosis in Germany. Suppose that one-tenth of such persons could be restored to comparative health through sanatorium treatment, and live three years longer to support their families. Upon the low wage-earning basis of $150 per patient per annum, after deducting the cost of maintenance of public sanatoria, it is estimated that the net gain to the State would amount to $2,000,000. As a purely business proposition, such a tuberculosis "trust" might prove as profitable as other life insurance enterprises. Even without such Utopian governmental aid, medical science is quietly working for the same economic end, and, to use a single illustration, within the past decade in the State of Massachusetts alone, the mortality from tuberculosis has been reduced by exactly one-half.

Typhoid fever and epidemic dysentery are now known to be completely preventable, and it is no fault of the science of medicine if the public does not always adopt the simple measures which would result in such an economic gain.

In Calmette's antivenene is another illustration of a medical discovery which may prove of great economic worth. In India 22,000 persons die annually, and 60,000 cattle die from bites of the poisonous ophidia. Many such deaths might be now preventable by prompt inoculation with antivenene.

Not least among the important aspects of medical science is the amount of capital invested in buildings and appliances for its pursuit and application, an amount exceeding that of any other pure science. Thus, in the medical and pharmaceutical colleges, research laboratories, health department bureaus, hospitals, asylums and training schools of this country alone several hundred million dollars are permanently invested in buildings, land and equipment, and scores of millions more are to be reckoned in endowment funds. At the present time the 125 "regular" medical schools of this country possess property valued above $18,000,000 and endowment funds exceeding $8,000,000. It is interesting to note that the schools of theology, while possessing property of nearly equal value with those of medicine, enjoy five times the endowment funds. The schools of law, requiring much less elaborate equipment, represent an investment of $1,500,000 in property and $500,000 in endowment funds.

To the value of medical college property may fairly be added that of the colleges of pharmacy, amounting to three-quarters of a million more in buildings and nearly $20,000 in endowment. The value of the 433 hospitals alone which maintain nurses' training schools exceeds $73,000,000 and their endowment exceeds $18,000,000. These figures represent probably less than one-fourth of the total hospital wealth, for many of the lesser hospitals are without training schools.

In the United States the 29 schools for the feeble-minded represent a property valuation of more than three and one-half millions. The 114 schools for the deaf own over $12,000,000, and the 37 schools for the blind $6,250,000 worth of property. These are all institutions which owe their origin largely to the development of medical science and which are, for the greater part, operated under constant medical surveillance and advice. I have not cited figures for the valuation of asylums for the insane and many special institutions, such as "diet kitchens," "fresh-air" institutions, convalescent houses, etc., which have derived their initiation from medical science, but have quoted data sufficient to demonstrate that three or four hundred million dollars is a conservative estimate for the vast property interests which, in this country alone, have grown up mainly during the past two generations from the co-operation of medical knowledge with humanitarian aims. How great is the need that these interests be fostered and expanded under intelligent guidance of the highest scientific order!

Turning to a more strictly mercenary, yet no less important resultant of medical progress, there should be added to the account the millions invested in the exclusively medical products, *i.e.*, the manufacture of antiseptics, disinfectants and legitimate pharmaceutical preparations, in surgical instruments, dressings and appliances, and instruments of precision. Collectively this enterprise, of quite recent development, constitutes a commercial factor of no mean proportions.

One of the great economic achievements of modern medicine, consists of the scientific study of the more or less helpless members of the community, the blind, deaf-mute and crippled, with a view to improving their condition and rendering them less of a burden to the tax-payer or the State. In 1817 the first school for deaf-mutes was opened in this country with 12 pupils. In 1900 there were 114 schools with 10,000 pupils. Recently the American Otological Association has assumed the systematic examination of all such pupils in the United States with already gratifying results

The munificent gift of Mr. Widener of

$2,000,000 for the establishment of a school in Philadelphia for the care and training in self-support of cripples has already led, in the eight years since its foundation, to the organization of similar schools in five other cities. It would be manifestly unfair to attribute the origin of such enterprises as these, exclusively to the influence of medical science in distinction from purely humanitarian motives, but without medical supervision they would be imperfect and incomplete.

The achievements of psychological physiology and pathology have not only produced a revolution in the science of psychology, but have accomplished many practical results in criminology and the treatment of the insane. For example, there is a marked tendency to make penal institutions less exclusively punitive and more instructive for the inmates. The solitary dungeon of medieval horrors has given place to penal institutions in which in many instances, there is attempt at rational classification of the inmates, and the influences of heredity, of environment and disease, are given their true weight. The health of prisoners is better cared for, and it is recognized that infection by tuberculosis should not be an inevitable outcome of protracted confinement.

Similarly in the care of the insane, the hopeless mad-house of old has, through medical enlightenment been replaced by well-ordered public institutions in which patients are not merely confined but are *treated,* with gratifying amelioration or cure of symptoms in not a few instances. It has been demonstrated that in nearly 90 per cent. of the insane the mind has become affected through errors of the body of the nature of chronic disease, alcoholism, or privation, errors which are often capable of early recognition and control.

In the department of hygiene and sanitation, medical science has newly established a wide field of industry. The public has been quick to adopt suggestions in this direction wherever they could be applied to profitable manufacture, but judging from the nature of the magnified advertisements which eclipse our landscapes, this phase of the matter is somewhat overdone. We are in less urgent need of patent "hygienic hair-brushes" than of intelligent methods of garbage disposal, less in need perhaps of patent foods than of proper policing our municipal water supplies throughout the country. Doubtless any genuine efforts toward improved hygiene are commendable, but it has long been the practice of mankind to prefer nostrums to cleanliness. The farmer still continues to drain the contents of barnyard and latrine into the household well, and then buy proprietary "tonics" for his ailing wife and children. But he will yet learn to mend his sanitary ways, as he is learning to mend his roads.

For the more serious problems of public hygiene and sanitation medical science is amply prepared to furnish definite, accurate rules which are completely practical and efficient, rules which cover every department—the hygiene of the person, of the home, of the school, municipal, rural, state, national, industrial hygiene, the hygiene of transportation, military and naval hygiene, and the hygiene of soils and climates.

It has been lately shown, especially in this city, that the place to check the spread of many infectious diseases is at the entrance to the public schools, and the prophylaxis of much anemia and nervous disease among school children is to be found in instructing their teachers in proper methods of heating, lighting and ventilating the school-room as well as in conditions of mental hygiene which will prevent strain, overwork and nervous collapse. Whether it be deemed wise or not to instruct the children themselves in rudimentary physiology and hygiene, their teachers should be masters of those subjects. By the impetus which medical science has given to these matters, the community may be not only spared many days of actual illness, but will find fewer weaklings among the rising generation of its citizens. In the hygiene problems of our large cities, we have much to learn and much to apply from the teachings of medical science. Medical science, the teacher, is ready, but the pupil, the public, is always late at school, if not an actual truant. In such case the more the economic, *i.e.*, the purely mercenary aspect of the situation can be emphasized, the more likely are many medical sanitary reforms to secure public adoption. Much has been accomplished, but still more remains, if we are to take the lead in matters hygienic and sanitary. For example, who shall say how our miles of subways are to be ventilated, for we have become a city of *boroughs* in more senses than one. Carbonic acid and other noxious vapors are heavier than air; how shall they be driven out and who wishes to live at the point where they are expelled? Why do we continually ride in public conveyances alternately closed to all needful ventilation or open to a raking end-to-end draught of ten miles an hour and crowded to the verge of indecency and physical injury? What is to be our sky-scraping future? To the vehicular perils of the street are added those of veritable tornadoes on windy days, and a sand-storm in the desert is not more dreaded than to face one of our antiquated uncovered ash-carts at such a time! The modern practice of building over almost the entire area of the lot makes it increasingly difficult to obtain sufficient sunlight and air for hygienic needs, especially for children, and in fact it is becoming more and more difficult for the well-to-do, whose children may not be turned loose in the streets, to furnish them with adequate exercise and fresh air, and maintain them in health throughout a winter's study. The atmosphere of hurry and tension which surrounds us all is difficult to dissociate oneself from and in many persons is productive of serious nervous strain. Such are but a few of the many local health problems which are the outcome of the increasing tendency to crowd into great cities, problems which were unimagined in the simpler life of our forefathers.

In the broader field of state, interstate and na-

tional quarantine there is also much to be accomplished. Both agriculture and commerce have preceded medical science in the establishment of national government departments with representation in the cabinet of the nation, but no earnest student of economics can fail to appreciate the value to the country—the purely commercial value, aside from the humanitarian—of giving to medical science the influence and force of that national authority in which the United States is still behind other nations.

No single municipality should be permitted to attempt the concealment, for its own unguided profit, of a pest-hole of a plague like the bubonic, as has lately been done in San Francisco. No State should be allowed to pollute with typhoid infection the waters of a stream flowing into an adjoining State, as occurred in the relationship between Pennsylvania and New York in the epidemic of Elmira. No town should be permitted to pour its typhoid-laden sewage, or, in fact, any sewage into inland lakes and streams, in selfish, nay criminal, disregard of its neighbors, as Ithaca has polluted the waters of Cayuga Lake. No town should be permitted to harbor a focus of smallpox infection through ignorance, or neglect of vaccination. With a National Department of Medical Science, endowed with reasonable and just authority, not only would such deplorable conditions soon cease but the other extreme of arbitrary, senseless quarantine, such as that lately proposed in the California Legislature against tuberculosis, would become equally impossible. Quarantine, both littoral and interstate, in so far as it might be needed at all, would be placed upon a rational basis of uniformity, and the commercial or economic gain would be incalculable.

One of the first duties of physicians should be to secure the establishment of local health boards wherever needed. They should insist that those who serve upon such boards should be men of scientific training, capacity and force, and finally, wherever such boards are in operation they should give them all the moral support and co-operation possible. By a system of prompt notification on the part of each practising physician and prompt response and ready distribution of statistical data on the part of the board, the confidence of the public will be won and its willingness to adopt sanitary reforms will be greatly promoted.

Another phase of this discussion is that of military hygiene and sanitation. It has been long recognized that in all protracted campaigns more men die from disease than from the implements of warfare. In active engagements this is to a great extent inevitable as a result of exposure to fatigue and hardship. One cannot profitably go to war in the tropics with a kerosene can and a bit of mosquito netting, as the Chinese do with a fan and paper umbrella, but in camp-life epidemics at least, are preventable. In 1897 (the year before the Spanish-American War), the Spaniards lost by death from disease in Cuba 32,532 men and 30,000 more were invalided home. A large majority of these deaths were due to yellow fever, typhoid fever, malaria and dysentery, all now known to be preventable diseases, and our marines at Guantanamo in the same country *did* prevent their occurrence absolutely the following year by simple sanitary precautions. The mortality from disease in early campaigns has been truly horrible. For example, in that of the English on the West African Coast in 1824 it was 69 per cent. of all men engaged; in that of the French in the Soudan in 1883-86 it was 28 per cent., yet in our own war with Spain it was only 2.5 per cent. and in Manila alone, 0.8 per cent. The disease mortality in the Crimea in 1854 was 23 per cent., but in the Franco-Prussian war in 1870-71 it was only 1.43 per cent. (Mosher). Of even greater importance to warfare than a low disease death rate, is the maintenance of a high standard of health efficiency among the men employed, and governments are realizing that the practical applications of medical science are as essential as proficiency in fighting. In the American Civil War the percentage of sick of the entire army was 20; in our last war in 1898 it was only 3.5. Even when due allowance is made for the different duration of these wars and the widely different conditions under which they were waged, the improvement in the general health of the men is very noteworthy.

The economic record of medical science in naval warfare is still more striking. In 1726 the British fleet in the West Indies, out of a mean strength of fighting force of 4,750 men, lost 4,000 from disease—a practical extermination of the force. In contrast is the report of the Surgeon-General of the United States Navy, covering the period of our war with Spain in the same tropical region, which shows better average health prevailing among the men than in times of peace. No small part of this contrast is due to the complete abolition of scurvy at sea which has, in former years, proved so disastrous to navies, the merchant marine and Arctic exploring expeditions. This one triumph of medical science alone has saved to the world's commerce and navies more than could be easily made comprehensible in figures. The influence of medical science upon allied sciences has been very great within the past two or three decades. Veterinary practice should properly be included under the broader interpretation of the term "Medical Science," and its achievements are producing enormous financial saving to the country through the control of such epidemic diseases among domestic animals as tuberculosis, the foot-and-mouth disease, glanders, hog cholera, and a long list of parasitic diseases like trichinosis, etc., which become a menace to man by attacking animals used for food.

It is not generally appreciated that medical science is producing a revolution in applied botany and agriculture. Arising from the discoveries of Pasteur and those who have made the germ theory practicable in methods of antisepsis and artificial immunity, has come the demonstra-

tion that many plants are dependent upon micro-organisms for their existence, organisms which within the soil associate themselves with the plant rootlets and by fermentation and other processes, actually predigest certain plant foods or prepare them for absorption. The question of sterility of a soil is no longer regarded in an exclusively chemical sense, but one which is directly comparable to sterility as the term is understood in referring to the micro-organisms of bacteriology. The entire physiology of plant life has been recently developed along parallel lines with animal physiology, and the study of the morphology, pathology and prophylaxis of the parasites of vegetation is closely allied with similar studies of animal parasites. In dairy products too, applied antiseptic cleanliness and antifermentative processes are the outgrowth of the recommendations of physicians who have been long teaching the lesson that cleanliness, health and pecuniary profit are not incompatibles but synergists. The various methods of food preservation by refrigeration, canning, drying, salting, preserving in syrups, sugars, vinegars, etc., although they in some instances antedate the science of bacteriology, are all explainable by it, their efficiency has been much improved by it, and to medical science the use of such products must be ultimately deferred to determine their inocuousness, or the dangers which may arise from their overuse or careless preparation. In other words, bacteriology, primarily and fundamentally a department of medical science, has been expanded through knowledge of it gained in medical research, so that it has developed an economic value in agriculture, animal industry and other large industries, which the imagination can with difficulty fully appreciate.

The science of biology had its origin in that of medicine, and for many centuries, physicians were the only biologists. In recent times many eminent biologists began their careers with medical training.

The science of meteorology has attained such independent distinction that it is almost forgotten that it owes its inception in this country to the methods of careful observation and record acquired in the medical service of the army. In 1816 Surgeon Benjamin Waterhouse, U.S.A., made the first series of meteorological reports under an order from the army headquarters. This work, extended by means of apparatus supplied in 1842 by Surgeon-General Lawson, developed into the establishment of a definite weather bureau in 1854, the observations being first made by army surgeons upon the climate and health in camps upon the frontier.

Medical science has opened a new field of industry for women, not alone in the practice of medicine but in the wide occupation of nursing, in which thousands of women find means of honorable and renumerative livelihood. In this country alone the pupils in the nurses' training-schools number more than 11,000, and the graduates 20,000.

Medicine, similar to other comprehensive sciences, has developed a voluminous literature, and a large financial interest is connected with its exclusive production. In 1774 American medical literature was represented by the total publication to that date of one new book and three reprints. To-day the output in medical sciences in this country is an average of one new book for each working day in the year, besides some 300 journals and 5,000 original journal articles per annum. In the libraries of the medical colleges alone (exclusive of the independent libraries like those of this Academy and the Surgeon-General's office), are 158,464 volumes. The mechanical quality of this work as shown in the art of printing and illustration is of a high order of merit which may favorably be compared with similar efforts connected with any other scientific publications.

It is asserted that medical science has prolonged the average age of mankind by several years during the past generation. Desirable as this achievement may be, it is outweighed by the greater gain in the ability to live while we do live, in healthful surroundings free from dread of plagues and with a foreknowledge of the causes of many preventable diseases. Someone said to me recently, "What is the use of doctors inventing new remedies to cure us, when they are always discovering new diseases to attack us?" This occasional attitude of the lay mind is due merely to a somewhat bewildering nomenclature, which, however, to the initiated is merely an effort at greater accuracy and finer differentiation. The patient who, ten years ago, might have grasped the conception of "anemia," would be bewildered beyond measure if he knew that his blood contained "polymorphonuclear neutrophiles" or gave evidence of "oligocythemia" and "poikilocytosis." For him it is still all-sufficient to know that his blood is "out of order." The only sense in which physicians can be said in any respect to have discovered new diseases is in the group of affections described as the "diseases of modern life," including the large variety of occupation neuroses, diseases caused by inhalation of dust and noxious vapors, various forms of acute and chronic poisoning arising from work in certain manufactures, drug habits, and nervous disorders attributable to the excitement and strain of competition under conditions of crowded metropolitan existence. Yet all these disorders medical science has fully met by suggesting methods of prevention and furnishing means of cure. Descriptions of phosphorus poisoning from match manufacture are no longer prominent in medical text-books as they were a generation or more ago. Chronic poisoning from arsenic, lead and mercury from working in the mechanical arts is capable also of complete prevention, as are many other occupation hazards.

Another aspect of medical science can be but barely mentioned in this review, namely the interest which the evolution of medical teaching bears for the students of pedagogy. At the period of the foundation of the first American

School of Medicine in Philadelphia, 138 years ago, of the 3,500 so-called practitioners of medicine in the Colonies, not more than 400 could be fairly described as educated physicians. Since that period we have passed through more than a century of struggling, poorly equipped proprietary schools, until by the earnest efforts of the medical profession itself, we have reached the only sound basis of medical training, the college which is a university department, equipped and administered upon broad university foundations. The student alike of history and of sociology cannot fail to find much of interest in a study of the evolution of organization and cohesion of the medical profession as illustrated by the history of its schools, societies and associations. There is a wonderful progress from the barber's basin to the equipment of a modern antiseptic surgical pavilion. In Noah Webster's elaborate "History of Epidemic Diseases," published in 1800, he expounds their etiology upon a basis of elaborate cosmological theories of earthquakes, comets, volcanic detonations and electrical atmospheric convulsions. What a development is there from such hypotheses to the exposition of medical science as presented at an International Medical Congress of to-day! Scarcely fifty years have passed since the public fought the practice of dissection by riots in New York City, and the States of New York and Massachusetts opposed it by every possible legislative obstacle. Up to 49 years ago a person detected in the act of dissecting a human body in the State of New York was liable to punishment by hard labor in state's prison (Samuel W. Francis; "Biographical Sketches of Distinguished Living New York Physicians").

Thirty years of bacteriology in all of its applications have done more for mankind than all the medical research that has preceded. In an estimate made by Alfred Russell Wallace of 25 discoveries of world-wide importance made during the nineteenth century, one fifth were contributed by medical science, and all but one of these, were made during the last half of the century, viz., anesthesia, the cellular doctrine, the germ theory, antisepsis and phototheraphy. Two more have been greatly influenced by medical science, viz., the theory of the antiquity of man and the doctrine of organic evolution. Yet we have not wholly emerged from the shadow of the Middle Ages, for have we not still among us those who would fain abolish such experiments as have made possible discoveries like those of vaccine, antitoxin, and antihydrophobic inoculations, even as there are those in Persia who would mob physicians seeking to check the spread of cholera.

If medical science produced no other economic benefit than to aid the restriction of the use of patent nostrums and the protection of a confiding public against wholesale quackery, it would be doing a noble work. Unfortunately success in this direction is far from complete, but without such restraining influence it is gruesome to contemplate the evil to which unlimited malpractices would attain.

I have thus far outlined the broader aspects of medical science as they may be summarized among the great factors in the world's progress of the day. I have purposely emphasized the economic rather than the humanitarian phase of this influence, for the former is usually of greater weight in a community in securing sanitary and hygienic reforms, in the enforcement of which, in the present state of public enlightenment legislation is often necessary. The humanitarian and medical achievements of the world are so interwoven and interdependent that they are bound to progress together. The skilful care of the sick is a foundation principle of civilization, but the care of the well, in order to prevent disease, forestall epidemics and avert physical suffering, is in many of its aspects a more modern thesis and one much more difficult for the community to grasp intelligently. Only within a very few years have those of large means begun to turn their attention to the importance of establishing and maintaining institutions of medical training, and especially of scientific medical research, as an opportunity for benefiting the community upon a truly magnificent scale; instance the Rockefeller Institute in New York City, as a foundation for pathological research, the Laboratory of Hygiene in Philadelphia, the Caroline Brewer Croft Fund for promoting the investigation of cancer, at the Harvard Medical School, etc. Of general hospitals we have enough for present needs, and in special hospitals nearly all separate classes of disease (excepting perhaps tuberculosis), are amply provided for. Of colleges for undergraduate training we have also enough; indeed it may not be deemed discourteous to say more than enough, but of facilities for purely scientific research for advancing barriers against the disease enemies of mankind, far too few. A single research like that of the lamented Major Walter Reid, in establishing the etiology and prevention of one of the most dreaded scourges of the human race, yellow fever, not alone ranks among the brilliant humanitarian achievements of history, but it cannot fail to impress the minds of practical men of wealth by its economic value as well. Such researches, like those of Pasteur and of Koch, who made it possible through their work of substituting for the spurious theory of spontaneous generation, the true doctrine of the specific nature of bacterial disease—such research has always proved of no direct pecuniary reward to the scientist. Its incalculable economic value, however, must surely, in due time, demonstrate to the philanthropist, that to invest in the endowment of medical research, is to realize the highest rate of interest for the good of mankind. In an address, delivered by Theodore Roosevelt while Governor of New York, at the inauguration exercises of the Cornell University Medical College, he said: "The work which is on the whole best worth doing for any great people is work which from its very nature cannot pay for itself. The great mass of the body politic has got to understand this, or there will be a failure to provide

opportunities for this non-renumerative work, the work which does not and cannot bring quick and profitable pecuniary returns to the doer of it."

The practical argument of this review is its application to the future of the Academy of Medicine. In surveying the economic value of medical science, one cannot fail to be impressed with its wide-reaching scope, as well as with its constantly growing influence. There is so much more in the science of medicine to-day, and all its correlated social problems, than was dreamed of in the limited pill-and-potion days of a hundred or even half a hundred years ago.

The record of the Academy in promoting the broader aims of this science is most commendable, but might we not in future accomplish much more? It should not be forgotten that it was the Academy of Medicine which by its influence secured the original organization of the Health Department of this city. It took active part in promoting the formation of the Sanitary Commission of the Civil War. It has through a special committee, repeatedly urged upon the Government the importance of establishing a National Board of Health. It has been instrumental in securing the reconstruction of the Quarantine Hospital and in securing free public baths for the poor, in preserving the city water supply upon sanitary principles, and has undertaken and accomplished many other good works of broad public interest, too numerous to further enumerate at the present time.

It might very appropriately fall within the scope of work of the Academy to include among its many sections one of Medical Economics, or Medical Sociology, with the special function of studying the broader aspects of medical science as affecting great public interests, studying them with the view to formulate conclusions and offer recommendations for action. Moreover, one or two of the general meetings of the Academy might systematically be devoted each winter to the open discussion of such topics. The public should learn more and more to look to the Academy as a Supreme Court in matters hygienic and sanitary. It would seem that the day has passed when such suggestions can be met by the plea that it is not the legitimate function of physicians to "meddle in politics," or to attempt to secure legislation for needed sanitary reforms and that our professional standards will be lowered by public campaign against flagrant abuses of the public health. The true disciple of Æsculapius is so imbued with the doctrine of the enormity of self-advertisement that he often shrinks from manifest public duty. While this doctrine is still earnestly applicable to the individual, the collective action of a representative body of physicians, such as compose the membership of this Academy, cannot be misconstrued. The whole subject of medical science is too broad to longer admit of narrow-minded criticism of the advocacy of sanitary reforms and betterments which may be instigated by the deliberations and through the influence of this institution. The Academy, which can refer with so much pride to its record in the past, need not fear to lower its dignity or lessen its purely scientific prestige by keeping pace with modern requirements and acting promptly and decisively as the sponsor of the public health. In closing, I cannot more appropriately emphasize this view than by quoting from the address delivered at the semi-centennial celebration of the Academy by that distinguished statesman who then honored us with his presence—Grover Cleveland: "We cannot keep out of mind the suspicion that if your professional work in exposing evils were more thoroughly supplemented by labor in the field of citizenship, these evils would be more speedily corrected. If laws are needed to abolish abuses which your professional investigations have unearthed, your fraternity should not be strangers to the agencies which make the laws. If members of your profession were oftener found in our national and State legislative assemblies ready to advocate the reform measures you have demonstrated to be necessary, and to defend your brotherhood against flippant and sneering charges of impracticability, the prospect of your bestowal upon your fellow-men of the ripened results of your professional labor would be brighter and nearer."

ETIOLOGY OF RACHITIS.

BY P. WM. NATHAN, M.D.,

OF NEW YORK.

The gross pathological anatomy of rachitis is well and definitely known; and it would add unduly to the length of this paper, were I to speak of it in detail. The lesions in the skeleton are the most constant and characteristic, and these must form the basis for any attempt to explain the nature and cause of this disease. These are therefore very briefly described:

The characteristic lesions appear at the growing ends of the long bones, causing a disturbance of the inter-cartilaginous ossification. These changes may be enumerated as follows: (1) defective calcification of the proliferating cartilage; (2) defective calcification of the new formed ostoid tissue; (3) increased vascularity; (4) hyperplasia of the proliferating cartilage cells. The vascular and hyperplastic processes are not, as has been shown by Pommer[1] directly connected with the pathogenesis; but are due to external and purely mechanical influences. The essential part of the pathological process is the defective calcification; for aside from the changes just noted the bone is normal. The ostoid tissue formed is in no way different from that formed in normal bones; the periosteum aside from defective calcification and changes due to mechanical influences, shows no change; the medulla of the bone is not altered; and contrary to the opinion of some authors the resorptive processes are not increased.

Pommer[2] has proved that the defective calcification is due to a dissolution of the previously

deposited lime salts in such rare instances that we may disregard it entirely; we must therefore conclude that, primarily, the bone lesions of rechitis are defective calcification of the cartilage and newly formed bone.

Up to the present time, no local condition has been found which can be considered the cause of the defective calcification. On the contrary, as I have pointed out, the local conditions in the bones are either secondary to it or are due to external physiological influences. Such being the case, we are perforce compelled to seek an explanation of the anomaly outside of the skeleton. And as the skeleton as a whole is uniformly and constantly affected in the same way, we must assume that this anomaly is of a general or constitutional character. This assumption is borne out by the other lesions and symptoms of rachitis: the enlargement of the spleen, the hydrocephalus, the nervous phenomena, the intestinal disturbance, the bronchial catarrh, etc., all point to a constitutional vice as the cause of the anomaly. Hence the etiology of rachitis must be sought in a condition or series of conditions, which are inimical to the calcification of the growing bones.

This being granted, the subject can be studied from two standpoints: we can assume that a constitutional anomaly is the cause of the inhibition of the calcium deposition, and attempt to explain the nature and cause of rachitis by investigating the cause and nature of this anomaly; or we can assume that a deficiency in the amount of the calcium within the organism is instrumental in producing not alone the faulty calcification but also the constitutional anomaly.

Ever since the discovery that rachitic bones are deficient in inorganic salts, the latter assumption has been the basis, or at least the starting point of the majority of the investigations on the etiology of rachitis. The deficiency of calcium within the organism has most frequently been attributed to one of two conditions; either the calcium of the food is deficient; or, that not being the case, the absorption of the calcium is defective. Experimentally, it has been definitely proved (E. Voit,[3] Roloff[4]) that total absence of calcium in the food, when the food is otherwise suitable, and sufficient in quantity, will induce the true rachitic bone lesions in growing animals. But such a combination of circumstances as total absence of calcium in a food otherwise suitable, does not occur naturally; and clinically rachitis cannot be said to arise from such a condition of affairs. The calcium in the human milk, the milk being otherwise normal, is always ample for the needs of the infant metabolism; cow's milk and all other "infant" foods, contain either sufficient or even an excess of this substance.

Consequently, if we still adhere to the theory of deficient calcium, we must assume that the absorption is defective. To prove this a vast number of experiments and researches have been attempted, and this theory has, I believe, been accepted by the greater number of medical men. Uffelmann[5] and Escherich[6] examined the feces of artificially fed children and found that the calcium was always greater in these than in the feces of breast-fed children, and they concluded from this that the calcium assimilation is not as perfect in the former as in the latter. That the absorption of calcium is defective in rachitic children seems, moreover, to be borne out by the investigations of Seeman,[7] who found that the amount of calcium in the urine of rachitic children is diminished. Seeman attributes the faulty assimilation to insufficiency of the HCl in the gastric juice. To account for this he adduces Bunge's sodium chloride theory, which supposes an excess of K in the food, causing an NaCl deficiency and consequently a deficiency of HCl secretion. Zander[8] believed that he had proved this assumption to be correct by demonstrating that in the milk of a number of mothers nursing rachitic infants, the relation of the K to Na was in favor of the K. In a very elaborate monograph on the etiology of rachitis Zweifel[9] has gone over this ground very fully, and he believes that he has placed the theory of deficient HCl and consequent faulty assimilation of calcium upon a firm basis.

By withdrawing the NaCl from the food (vegetable diet) of nursing women he hoped to induce a NaCl deficiency, which, he argued, would have a twofold effect. In the first place it would diminish the amount of calcium assimilated by the mother, and thus diminish the amount in her milk; in the second place it would diminish or eliminate entirely the supply of sodium chloride to the child, which in turn would inhibit its power of absorbing calcium. Thus he hoped to induce rachitis. His results, however, were not favorable; and he found that the reason for this was that no matter how strictly he eliminated the NaCl, the maternal organism was still able to extract a sufficient amount from the food to keep the quantity in the milk within a certain limit. Nevertheless he considers Zander's and Seeman's observations conclusive; and concludes that in nursing infants rachitis is caused by a deficiency in the HCl and a consequent malassimilation of calcium. That such a lack of NaCl in the food of nursing mothers can occur under other than experimental conditions he considers proved by the fact, that in Saxony, where it is a national peculiarity to take black bread without salt, rachitis is unusually frequent and of an unusually severe character.

However, as these observations are capable of explaining the pathogenesis of rachitis in nursing infants only, if at all, he proceeded to investigate the relation of these facts to artificially fed infants. In order to discover the fate of the calcium after its ingestion, he performed a very extensive series of test tube experiments in the digestion of cow's milk. As a result, he found that the dissolved calcium salts of the cow's milk are, to a very large extent, changed into insoluble combinations when the milk is coagulated by the milk-curdling ferment. When the milk is boiled, the amount which becomes insoluble is even

greater, so that the quantity of soluble calcium which remains after coagulation is below that contained in an equal quantity of human milk. The insoluble calcium salts in the milk curd can be redissolved in only one way, that is, by the presence of an acid—in the case of the infant's stomach, HCl. It depends, therefore, upon the quantity of HCl in the stomach whether or no, a sufficient quantity of calcium is made soluble and absorbed. If the HCl is deficient a calcium deficiency occurs in spite of the excess of calcium in the cow's milk. From this he concludes that, whenever, either as a result of the action of Bunge's law, or as the result of a primary deficiency of NaCl, a deficiency of HCl occurs rachitis will be induced.

Zweifel's monograph is very interesting and embodies a vast amount of time and work; moreever it represents the highest development of the theory of deficient absorption of calcium as the cause of rachitis. However, in spite of the accurate and scientific manner in which his individual experiments were conducted, this hypothesis must inevitably fall to the ground. Granting that the experiments themselves and the conclusions to be drawn from them are perfectly scientific and accurate; as a complete entirety the theory is false; necessarily false, because the premises upon which it is founded are fallacies.

Zweifel assumes, upon what ground he does not state, that the HCl secretion is absent or very deficient in early infancy, and continues so for some time after, though there is abundant evidence to the contrary. He also assumes that besides the natural deficiency, a further deficiency is induced by lack of NaCl within the infant's organism, and adduces Bunge's[10] law to prove this.

As far as the latter assumption is concerned, it takes very little insight to appreciate that Bunge's law has only a very limited application in this respect. Excess of K, in the food no doubt produced a NaCl loss within the organism, by the combination of the K with the Cl and the subsequent excretion of the KCl thus formed; but this replacement of the Na by the K only continues so long as the NaCl within the body is in excess of what is absolutely necessary to the organism (Cv. Voit).[11] Otherwise the organism tenaciously holds its NaCl; and unless very unusual and very unnatural conditions prevail, there is always a sufficient quantity retained to prevent NaCl starvation. Zweifel's own experiments prove this; for although he forced nursing mothers to consume vegetable food, poor in NaCl, and eliminated all other sources of NaCl, he was unable to reduce the NaCl in the milk of the mother, or that in the urine of the child beyond a certain point; that is he was able to induce NaCl deficiency in neither mother nor infant.

However, even were it true, which it is not, that by the entire elimination of NaCl, except that naturally contained in the food, NaCl starvation could be induced, this would not prove that NaCl deficiency is the cause of rachitis. Such a peculiarity as eating food without the addition of salt does not exist, even among the most poor and destitute. That the black bread of Saxony is baked without salt does not indicate a general tendency in this direction; Zweifel himself considers this a local peculiarity. Yet rachitis, as all medical men can testify, occurs in nursing infants outside of Saxony, and in this country where we are particularly partial to salt, it certainly is not rare.

But even were we to assume that a NaCl deficiency could occur from natural causes this would not constitute proof that such a deficiency is the cause of rachitis. It would first be necessary to prove that the calcium is absorbed in the stomach; and could only be absorbed if it were dissolved by the HCl contained in the gastric juice. But this has never been proved; on the contrary such an assumption is opposed by a number of physiological facts. In the first place only a very small amount of calcium is taken in, and is necessary for the organism, no matter how much is present in the food ingested; secondly all dissolved calcium salts if absorbed are precipitated by the alkaline body fluids. These and other physiological considerations lead us to conclude that only a very small amount of calcium, which is in combination with organic substances, thereby retaining its solubility, is assimilated.[12]

These theoretical considerations are, I think, more than sufficient to show that the deficient NaCl hypothesis is untenable. However, leaving them aside, I believe the experiments and observations of which I shall give only a summary here, make it certain that, while the bone lesions of rachitis may be induced by the elimination of the calcium from the food, such an absence of calcium from the food is not the cause of clinical rachitis; that in fact the lack of calcium cannot be held responsible for its causation at all.

According to those who hold the theory elucidated above, rachitis is due to a deficiency of calcium within the organism; this deficiency, they assume arises, not because of a lack of calcium in the food, but because the calcium therein contained is not absorbed. Now Rüdel's[13] experiments prove conclusively that even in the severest forms of rhachitis, soluble calcium is absorbed in the same proportion as in health; so that as Zweifel contends the root of the trouble must lie in the insolubility of the calcium salts contained in the food. Hence if this contention is to hold, rachitis cannot supervene so long as the organism has a sufficient amount of calcium at its disposal.

I have been fortunate enough to be enabled to put this contention to such a test. I have had under my observation three infants of about the same age (12, 12½ and 13 weeks respectively), whose mothers were either compelled or for other reasons decided to take their infants from the breast. Two of these infants were perfectly normal, the other had symptoms of insufficient nourishment. These three infants were then fed upon condensed milk, a teaspoonful of milk to

twelve of water, which later was reduced to ten teaspoonfuls. Besides this food, there were given soluble calcium phosphate, the monobasic calcium phosphate and sodium chloride; this was given in the form of a mixture.

R Monobas. calc. phosphate
Nat. chloride, aa..... 3.0 (gr. 45)
Syr. simplicis
Aquæ, aa..... 30.0 (℥)

to be administered three times a day one-half hour before feeding, that is, upon an empty stomach. Thus these infants were receiving an excess of soluble calcium and in addition, sodium chloride, to increase the hydrochloric acid in the gastric juice, so that (if Zweifel's view is correct) an additional amount became soluble from the calcium contained in the food. Now mark the result.

These infants were kept under observation for about one and a half years. At first all three did fairly well, they gained in weight, took the food readily, had no signs of gastro-intestinal disturbance, and apparently were perfectly comfortable. During the middle of the fifth month, however, two of the children began to show signs of illness. They cried more than usual, showed a disinclination to being handled, and were constipated. By the middle of the sixth month, both children had begun to sweat and bore the head into the pillow, and by the middle of the seventh month both had pronounced signs of rachitis, *i.e.*, enlarged epiphyses, prominent abdomen, bearing of the ribs, suggestion of Harrison's groove, etc. It seems remarkable, but nevertheless true that the third infant, the one who at the beginning showed signs of insufficient nourishment, was at the time the condensed milk was discontinued, perfectly well, showing absolutely no signs of rachitis.

Early in the eighth month, the condensed milk, and at the same time, the administration of monocalcic phosphate and sodium chloride were discontinued and the children were placed upon a diet of cow's milk in the proportion of three-quarters milk to one-quarter water. This mixture received no other addition, was sterilized (?) by simply allowing it to boil up once over the free fire—allowed to cool and placed upon ice until required for use when the quantity to be used was warmed. Upon this diet, which was soon augmented by eggs and cereals, the rachitic infants immediately began to improve; they gained in weight, cried less and less and the symptoms and signs of rachitis gradually disappeared.

I think there can be no doubt at all that these observations are conclusive. Here we have two infants, with an abundance of soluble calcium at their disposal; not alone at their disposal but ingested in such a manner as to render it impossible for non-absorption to take place, if absorption ever takes place at all. Nevertheless these infants became rachitic. And what shows still more clearly how small a part the soluble calcium ingested with the food plays in the production of rachitis, the cessation of all the extra ingestion had absolutely no influence in retarding the recovery from rachitis, so soon as the infants were given a more suitable food. More conclusive evidence against the theory that the calcium itself or the NaCl indirectly, are concerned in the production of rachitis could not be desired.

Nevertheless, for fear that these observations may be considered too few to be of value, I have adduced further evidence to support this contention. If, again, we assume that the calcium deficiency is the cause of rachitis, we must conclude that, other things being equal, the rachitis must disappear as soon as the calcium deficiency is compensated. With a view of testing this conclusion, I have tabulated the results of various forms of treatment in rachitis, including that of the administration of soluble calcium phosphate.

I have records of 803 cases, of which 203 were seen only once or twice, and are therefore not available for our purpose; 123 are not considered here, for reasons which I shall speak of in another paper. Of the remainder 150 were seen prior to 1901 and were treated according to Kassowitz with phosphorus: 50 (seen during the winter and over six months old,) were given cod-liver oil; 150 were given monobasic calcium phosphate, in the manner described above; and 127 received no medication whatsoever.

All the children were, so far as is possible in polyclinical practice, placed upon a uniform diet. A number of the mothers, the most ignorant and careless, probably did not follow instructions, but the majority of them were, I believe, conscientious and any lack of favorable results in the treatment must be ascribed to other causes. Infants over three months (there were none younger) were given three-quarters milk and one-quarter water, to which was added sugar of milk in the majority of cases, and treated in the manner above described. If three-quarters milk caused gastric disturbance the quantity was reduced for a time, but soon gradually increased again. The period of observation always exceeded one month.

It takes only a cursory glance at the tables to convince anyone that there is a remarkable uniformity in the results of treatment. The percentage of improvements varies only slightly with the various forms, being slightly higher without medication, and lowest with the administration of phosphorus. That the calcium phosphate has no greater curative influence than other therapeutic measures is evident from the fact that improvement was no more frequent when it was administered than when nothing at all was given.

These practical observations, therefore, bear out the theoretical consideration. The latter lead us to believe that the organism is not dependent upon the soluble calcium, in fact, the physiological consideration shows that it receives it almost entirely in the form of an organic compound with albumin. However, even should the absorption of the calcium be dependent upon its solubility, there is no reason to believe that the infant is un-

able to secrete sufficient HCl to bring it into solution. The former, (*i.e.*, the practical observations), show conclusively that infants can, and do become rachitic in spite of an abundant supply of absorbable calcium, and that children with rachitis are not cured any more rapidly when an excess of absorbable calcium and sodium chloride is supplied them, than when these are omitted.

We must, for these reasons, conclude that a deficiency in the quantity or a faulty absorption of the calcium ingested is not the cause of rachitis.

Such being the case, and our only clue to the etiology of rachitis being the faulty depo-

sition of the lime salts in the bones, the assumption (mentioned first at the beginning of our discussion) that an anomaly of the metabolism, which besides causing other abnormalities, is inimical to the normal calcification of the bones, must form the starting point of our search for the cause of rachitis.

How such an anomaly is induced is difficult of explanation. Moreover, it will remain difficult or impossible to explain, until we have a better understanding of the nature of the anomaly than we have at present, *i.e.*, until we have a more definite knowledge of the pathogenesis of rachitis. In this respect we are, as Vierordt[14] aptly remarks, still completely in the dark.

My original intention was to take up this portion of the subject this evening. I flatter myself that some of my observations are likely to throw some light upon this mystery. However, the time alloted does not permit of this and I must therefore reserve the exposition of this part of the subject for a future paper.

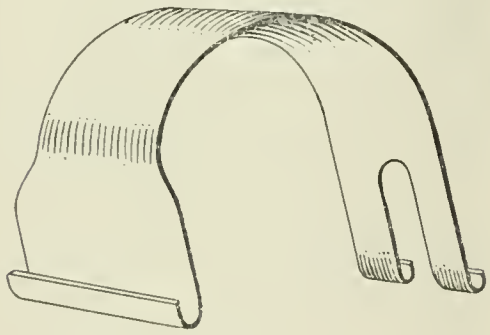
Treatment of Hemorrhoids.—It is somewhat singular that a method can be described as "new" which has been in vogue for a considerable time. JOHN LANDSTROM (Zentralbl. f. Chir., Nov. 21, 1903) describes the use of the angiotribe in the treatment of this condition, which he says he introduced in September, 1902. He states that the operation is much more desirable than either the cautery or the ligature—first, because of its certainty, and second, because of the speed with which it can be accomplished.

SPLINT FOR TREATMENT OF FRACTURE OF THE INFERIOR MAXILLA.

BY CLINTON B. KNAPP, M.D.,
OF NEW YORK.

During my service as interne at the French Hospital, we had two cases of fracture of the lower jaw which gave us considerable trouble to keep in proper position. The anterior fragment being pulled downward and backward by means of the muscles attached to the hyoid bone. The posterior fragment being displaced in the opposite direction due to the pterygoid, masseter and temporal muscles. Many attempts were made to keep the ends approximated by means of various bandages, on the principle of the old four-tailed bandages; these pull backward as well as upward, whereas traction upward and forward was needed. To accomplish this I took a strip of tin, turned up one end to form a gutter, carried the strip from the forehead over the vertex and well under the occipital protuberance. This was made secure by a plaster-of-Paris bandage.

Fig. 1.



Strips of adhesive plaster from the under surface of the chin to the gutter of the splint gave the desired upward and forward traction, thus getting apposition of the fragments and perfect position of the jaw. Adhesive plaster has the advantage of not slipping. The posterior part of the splint passes down on either side of the occipital protuberance so that the patient has no discomfort from pressure.

Case I.—T. W. N., thirty-five years old, entered the French hospital Feb. 21, 1903, during the service of Dr. E. H. Pool.

The fracture, the line of which was from a point behind the teeth on the right side, downward and backward, was received in a fight ten days before coming to the hospital. Previous to his entering a number of attempts had been made to set the fracture, among them an interdental splint had been tried, without success. After entrance various bandages were applied, also with no success. The tin splint held the fragments in perfect apposition with no further trouble. Removed at the end of three weeks, with good result.

Case II.—S. H., twenty years old, entered the hospital Oct. 6, 1903, during the service of Dr. Charles H. Peck. Fracture on right side through the lower part of ramus, the result of a fight. Splint removed at the end of three weeks. Result good.

Fig. 2.

Dr. Charles H. Peck presented the last case for me, together with the splint, at the Surgical Society, on Nov. 11, 1903.

With this method of treatment the patient has free movement of the head. The splint is very light, easily made and easily applied.

THRUSH.

BY H. ILLOWAY, M.D.,
OF NEW YORK;
FORMERLY PROFESSOR OF DISEASES OF CHILDREN, CINCINNATI COLLEGE OF MEDICINE AND SURGERY; FORMERLY VISITING PHYSICIAN TO THE JEWISH HOSPITAL, CINCINNATI; MEMBER OF NEW YORK ACADEMY OF MEDICINE, ETC.

Though most frequently a trifling affection that is readily cured with the aid of some simple remedy it may nevertheless at times become a very serious trouble, so serious indeed as to threaten, aye, even to take the life of the child.

Thrush is a disease of filth, of uncleanliness on the part of the mother or nurse or whoever may have charge of the infant; uncleanliness of the breasts, uncleanliness of the nipple and of the nursing bottle, uncleanliness as regards the general hygiene of the child. One of the worst cases that I met with was in a fairly well-to-do family where the grandmother, a foreign woman accustomed to the res angusti domi and the squalor and filth of the paupers of Northern Europe, took charge of the new-born babe. She abhorred water and thought the infant must be of the same mind and instead of washing it smeared it over with butter. She put her fingers into the infant's mouth without any previous cleansing, regardless of what she might have been doing before. It was impossible to change her methods, she had had children, had reared several and certainly knew what to do. The small pieces of muslin

which she prepared wherewith to cleanse the child's mouth she cut from a piece that had been rolling about the goods' table for some time, and kept them, so as to have them handy, under the mattress of the infant's cradle. The breasts of the mother were also not exposed to the dangers of a cleansing with water, but were likewise smeared with butter (taken from that upon the table for common use), as the daughter, like the mother, thought this the safer practice. As a natural consequence thrush supervened, became more and more intense and after a period of some weeks carried off the babe by inanition.

The disease once present, it is again the carelessness of mother or nurse that tends to its spreading and therefore its aggravation. The parasite, the *Oidium albicans*, is readily propagated, and a small particle thereof transplanted elsewhere and given an opportunity to become adherent will soon produce an abundant crop in the new locality. The cleansing of the infant's mouth is usually done with the finger wrapped with a piece of muslin or linen, and in the treatment of thrush the topical applications are in most instances made in the same manner. Usually the process is immediately repeated, two applications, one immediately after the other, being thus made. In the performance of this act more or less of the parasite is detached and adheres to the cloth and not infrequently the epithelial covering at one or the other points is abraided. Now, if it be done by an ignorant and slovenly person, no particular care is had as to the cleanliness of the cloth with which the finger is wrapped and after the first application, the soiled cloth instead of being replaced by another —by a clean one, is allowed to remain, dipped into the mixture and the application repeated. The detached particles of the parasite are thus reintroduced into the mouth. Of these some may become replaced while others, falling loose into the mouth, are, as the infant does not spit out, carried backward to the furthermost portions of the dorsum of the tongue, to the fauces, to the pharynx and even to the esophagus.

That uncleanliness of the mother or nurse, both as regards her own person and that of the infant, is the factor in the production of this ailment cannot be questioned to-day and is amply demonstrated by the following facts:

1. It is now a recognized fact that the disease may develop in an infant otherwise healthy and with an oral cavity in a normal state (and not, as was formerly taught, only in infants ailing in some way or other and with the mouth more or less inflamed).

2. Since the better knowledge as regards the care of infants has become more widespread among the laity the disease has become of rather rare occurrence in this country.

3. Even in the many grave cases of gastro-intestinal disease, which I met with in a long series of years, which is particularly frequent in the summer and which is supposed to favor the development of thrush, careful attention to hygienic requirements, wherever faithfully given, prevented its development.

4. The parasite is always introduced from without.

The infant thus afflicted will not or cannot nurse. Whether this is due to an irritated condition of the tongue and other parts of the buccal cavity following upon the invasion and making suction painful or whether it is due merely to the presence of the parasite which either takes away the appetite or develops a bad taste in the mouth and therefore a dislike for the food, is a question that has not been determined. To me it would seem, judging from the cases here reported and a few others, that it must be due to the presence of the parasite for in these cases very shortly after the mouth was freed therefrom the infants began to nurse again and with a right good will.

As a consequence of this refusal of food inanition soon sets in and a rapid deterioration of vitality ensues.

Of course the further down the parasite spreads the more serious becomes the case and when it has reached the esophagus the condition may be said to be hopeless, the infant starves to death.

The treatment of the lighter forms of thrush, where the parasite has as yet spread but little and its threads have not yet penetrated the epithelial layer, is not a very difficult matter. In common use with practitioners and laity is borax in some form either in solution or as a paste made with honey, as recommended by Trousseau[1] and applied with the finger as above described. Some indeed, upon the ground that the parasite thrives only in an acid medium, content themselves with the application of Vichy water or of solutions of Soda bicarbonate. Early in my experience as a medical practitioner, seeing the evils that attended the applications made with the finger, I preferred to use the hyposulphite of soda which was supposed to possess marked antiseptic properties.

℞ Soda Hyposulph..... ℈i
Ag. Destill.....ʒv
Glycerin..... ..ʒiii
M. Sig.: One teaspoonful every two hours

administered internally and applied topically with a large camel's hair pencil. In the ordinary cases and even in some where the parasite had already attained considerable extent this agent gave me excellent results, better than those usually obtained with the borax.

However, it is not these lighter cases that are the source of worry and trouble. It is where the parasite has spread largely, where its threads have sunk down deeply into the tissues and feeding becomes almost impossible that the question arises what can we do to save the humunculus.

Various of the more potent remedial agents have been recommended: Trousseau[2] advised nitrate of silver and this agent seems to be the favored one as yet with many pediatrists; while J. Lewis Smith[3] prefers the use of

℞ Zinc sulphate.....grs. ii to iv
Aq. Rosæ .....ʒii

A weak solution of mercury bichloride in alcohol, to be applied with the finger as described. It is said that one or two applications are effective. A dangerous remedy, except in the hands of the most expert, and even then its success has not been such as to commend it to physicians in general.

Application of the perchloride of iron once a day or every second day (Comby[4]).

A solution of potassium permanganate, 1 in 25 topically and the administration (internally) of a solution of resorcin 1 in 100 three to four teaspoonfuls in twenty-four hours (Baginsky[5]).

None of these agents have that certainty of effect and that rapidity of action needed in these severe cases where every moment lost is of grave detriment to the starving child confronting us.

Lately Vladimiroff[6] recommended that the parasite be forcibly removed by means of the dry swab and the forceps and the parts then brushed with a two per cent. solution of silver nitrate. He admits that the procedure is a rather brutal one but fully justified by the exigencies of the case.

In the course of practice I came across such cases now and then and after several failures with various methods of treatment it occurred to me that the remedy which was then known to us as the best antiseptic, namely iodine, and which with many of us, as with me, was the standard application in the various anginas, was the remedy par excellence to apply. Fortune favored me and soon gave me the opportunity for a trial. I made it, and all expectations were realized. One thorough application and the parasite was removed.

Case I.—March, 1881. I was called to see Baby K. Its mother a woman in very modest circumstances, was delivered of it six days ago by a midwife and it then appeared a healthy and well-developed infant. There was nothing extraordinary about the confinement, in fact, as I was told by a neighbor woman experienced in these matters, it was rather an easy one, and although subsequently things ran on smoothly, the lochia normal, the breasts filling with milk, though not abundantly, no fever at any time, the mother seemed to fall into a state of listlessness, of apathy and had no care for the infant or anything else. The care of the baby, outside of the visits made by the midwife once in the morning, devolved upon a little girl eight years old (the father was away in the country peddling).

At the outset the baby had nursed well but later on it seemed to have some difficulty in doing so. In the last twenty-four hours, when put to the breast it would take hold of the nipple, hold it for a little while, making but feeble effort at suction, and then let go.

Examining the infant's mouth I found it affected with thrush. Otherwise everything seemed normal. I prescribed the borax and honey preparation as perhaps the easiest of application under the circumstances and directed the mother to apply it three times a day giving her detailed instructions therefor.

To make a long story short, the mother paid no attention to the baby despite all my scoldings, remaining all the time in bed in the same apathetic state; the little girl did the best she could and when I called for the third time, on the fourteenth day (of its birth) I found the whole tongue back to its root covered with the parasite, and small patches on the gums and on either cheek. The infant had not nursed at all for the last twenty-four hours and hardly at all the days preceding that. It thus got but little nutriment outside of a little sweetened fennel (seed) tea which the little girl gave it with a teaspoon several times a day. It was very weak, cried in a low wailing tone and showed a considerable loss of flesh. It was evident to me that more effective treatment was required if the baby's life was to be saved. I sent to the drug store and had put up the following:

℞ Tinct. Iod. ..... ℥ss
Glycerin. ..... ℥iiiss

As soon as it was brought I applied it with a large camel's hair pencil to the tongue, gum and cheeks. The effect was remarkable; the parasite seemed to melt away as it were and when I was through not a vestige remained.

I now pulled the mother out of the bed (literally) and made her get into her clothes. I directed her to sponge herself, particularly her breasts, very thoroughly with soap and water, rubbing dry with a clean towel. To do this every morning and to use a fresh towel for drying each time. This was as much as could be expected. After an hour or so she was to put the child to the breast and to do this regularly at intervals of two hours, etc.

I called the next day, found no trace of thrush and was told that the infant had nursed well throughout the day and twice in the night. To make sure of this I had it put to the breast in my presence and was thus convinced that it nursed very well, with evident relish as if it realized that it had to make up for lost time. The mother also seemed to have recovered all her former energy.

Case II.—October, 1883. I was called to see Baby M., three weeks old. Its mother, now a widow, is compelled to go to work daily for the support of her family and with the exception of morning and night nursings the baby is fed with a bottle, condensed milk being its food. Its care throughout the day devolved upon a twelve-year-old girl.

Up to the fifteenth day the baby nursed and took its bottle with much vigor and throve nicely. On that day the little nurse noted that her baby brother did not seem as eager for the bottle as he had always been previously. However, he nursed the breast well. A little later it nursed but little, taking hold of the nipple, making a few suctions and then letting it go again. In the last two days it would not take the bottle and did not nurse

the breasts, and all the nourishment it has received in that time has been what the mother squeezed out of her breasts into its mouth.

Examination of the mouth shows extensive thrush all over the tongue to its root with small patches upon the fauces and upon the cheeks.

Treatment.—The iodine mixture was applied thoroughly wherever the parasite was found and after the brush was withdrawn the parts looked red, slightly irritated, but clean.

Minute directions were given the mother as to the necessity for cleanliness of the breasts and of the bottle and how to care for the latter.

I saw the baby some three or four days later; no further evidence of the disease. The child again took the bottle very well and nursed the breasts with all its pristine vigor.

I have seen other cases since, treated them in the same way and all with the same happy result.

At the outset I was inclined to ascribe all the virtues to the tincture of iodine, regarding the glycerin as a convenient vehicle only, but since then I have discovered that the glycerin is also a very important factor, as it certainly loosens up the mycelium from the tissues to which it is attached and makes its removal an easy matter. Without exaggeration it can be said that this plan of treatment surpasses any that has hitherto been recommended in the readiness of application, the harmlessness of the remedial agent employed and the marvelous rapidity of its action—truly *cito, tuto et jucundo.*

THE INTERNAL TREATMENT OF DISEASES OF THE BLADDER.

BY LOUIS STERN, M.D.,
OF NEW YORK.

While in cystitis local measures have to a great extent superseded the internal treatment, the latter is not as unimportant as some authors are inclined to think. In the old materia medica the so-called urogenital remedies occupied a prominent place. They were employed indiscriminately in most genito-urinary diseases, and at that time regarded as almost indispensable. Nowadays, however, their use finds but limited application, and in much smaller doses than those in which they were formerly prescribed.

The tendency at the present time is to regard affections of the bladder and urethra, and the prostatic troubles with which they are so often associated, as chiefly of bacterial origin. This has had a corresponding influence upon the internal treatment. Until the introduction of hexamethylene-tetramin, which is known commercially as urotropin, formin, aminoform, cystogen, etc., there was no drug which could be regarded as an internal antiseptic in the true sense of the word. In fact, the only drugs of this kind which have been administered are benzoic acid, salol, and boric and salicylic acids, and these are not sufficiently powerful to produce any marked destructive action upon microorganisms in the urinary tract. On the other hand, hexamethylene-tetramin has the property of setting free formaldehyde during its process of elimination through the urine, and thus bringing this powerful antiseptic directly to bear upon the source of the infection. It therefore quickly found its way into genito-urinary therapy, and for a time seemed to leave nothing to be wished for. Then came reports of its irritating the kidney and producing hematuria and albuminuria and disturbances of the digestive organs. It was also found that in certain cases in which the urine was strongly ammoniacal the drug was not decomposed and did not yield up its formaldehyde. Unfortunately, these were often the very cases in which its action was most desired, so that there was considerable room for improvement, and when a new derivative of hexamethylene-tetramin, known as helmitol, or hexamethylene-tetramin anhydromethylene citrate, was brought forward, which seemed to possess some important advantages, I was not loath to give it a trial.

My experience with the new drug has now extended over six months, and during that time I have had occasion to frequently test it and convince myself of its merits. Compared with hexamethylene-tetramin, I have found that it can be given in much larger doses without exciting irritation and that it is more uniform in its action; in fact, the reaction of the urine seems to exert no influence upon its sterilizing effect, and this factor can be ignored during its administration.

In most of my cases I have had no opportunity to make thorough examinations of the urine, so that I was unable to determine its degree of antiseptic power; all that I know is that in cases in which the urine was turbid and filled with mucus and pus, it rapidly cleared up and lost its offensive odor.

The drug also seems to have some pain-relieving quality, for even before the urine had become perfectly sterile the tenesmus was often greatly diminished.

I have recently read an abstract of an article that appeared in a German journal detailing some comparative experiments with hexamethylene-tetramin and helmitol in the Hygienic Institute of Zürich, in which the author, Dr. Müller, after a series of thorough tests, found that the latter had a much more pronounced antibacterial action than the former. All my experience, however, has been purely clinical, and is recorded in the following observations, the only ones of which I was able to keep notes:

Case I.—Mr. J. C., sixty-nine years old, had suffered for several years with bladder trouble and more or less tenesmus. When I first saw him (May 15, 1903) he was passing his water

about every hour, and complained of considerable pain during the act, and only voided two or three drams at a time. He passed in my presence about 3½ drams of urine, which was very turbid and ammoniacal, and contained considerable mucus and pus. Examination of his urethra revealed no stricture, but on examining per rectum I found enlargement of the left lobe of the prostate. Treatment was initiated by gentle massage of the prostate, and 15 grains of helmitol given four times a day. I saw him again on May 17, and learned that he was no better; it seemed as though the urine flowed a little more freely, but try as he would he could not pass over three drams in my office. I did not massage his prostate this time, but waited until May 19, when this procedure was thoroughly carried out. Up to that time he had been unable to pass more than three drams of urine, which had not shown any improvement thus far. On May 23 the patient returned, and on this occasion he passed 6½ drams of urine, which was much less turbid and neutral in reaction. The prostate was again massaged and he was given 15 grains of helmitol every three hours until 75 grains had been taken. The additional 15 grains seemed to help him very much, for on May 26 he voided in separate glasses about 8 ounces, which was almost clear and of slightly acid reaction. The tenesmus had greatly diminished, and he was able to hold his water for longer intervals. The prostatic trouble had not improved thus far under treatment, which was continued. May 30, the condition was not much changed since his last visit, only that he said he felt much better and that during the night he did not have to get up as often as formerly. June 2 he passed 7 ounces of urine in my office, which was slightly acid and almost clear, the ammoniacal smell having entirely disappeared. His prostate was smaller and he said he had only been up three times the previous night to pass his urine. I reduced the dose of helmitol to 15 grains, four times a day, but still kept up prostatic massage. June 5, patient returned well pleased. The urine was entirely clear, neutral in reaction, and was passed at much longer intervals, only once at night. The prostate had further diminished in size, although not quite normal. The dose of helmitol was now reduced to 15 grains, morning and evening. June 9, the symptoms had all disappeared and he had slept for seven consecutive hours without awakening, something he had not done for three years. The helmitol was then discontinued, but the massage kept up for several more weeks. At that time the urine was neutral, perfectly clear, and contained no pus or mucus. July 2 he was discharged from treatment.

Case II.—Miss M. A. R., chorus girl, consulted me, April 14, 1903, complaining of considerable burning when passing her urine, which was quite frequent. On examination I found an acute gonorrhea which had invaded her urethra. I gave her a hot saline douche, painted the whole vagina with a 4-per-cent. protargol solution, and inserted a dry cotton tampon. Helmitol, 15 grains, was prescribed, four times daily, and she was instructed about her diet, etc. On the following day I repeated the treatment, and instructed her that on removing the tampon she should take a hot douche. This treatment was continued up to the ninth day, when the burning had entirely disappeared, though the discharge had not all ceased. The dose of helmitol was reduced to 15 grains, three times a day, and the vagina swabbed with a 6-per-cent. protargol solution. On the seventeenth day I discharged her as cured.

Case III.—Mrs. R. J. C., came to me with the following history: She was passing urine about every hour, had more or less tenesmus, and had a dull feeling over the pubes for the past six months. She was unable to void urine in my office, so I drew off about two ounces. It was very ammonical and filled with pus but no sugar or albumin. Treatment was begun by washing out her bladder with a ½-per-cent. solution of protargol, using about 11 ozs., and prescribing 15 grains of helmitol four times daily. She returned in two days without marked improvement. Treatment was continued. On her next visit, three days later, she stated that during the night while on the commode she felt as though she had passed a large lump of something, which she brought to me, and which, on examination, was found to be a mixture of blood, pus and mucus. I again washed out her bladder with a 1-per-cent. protargol solution and continued the helmitol. She called the following day and said she felt better than she had for over six months. Examination of the urine showed that the pus had diminished one-half. The tenesmus had subsided entirely, and the interval between urinations had lengthened to about two hours. I kept up the original treatment for the next six weeks, and at the end of the fourth week the urine was entirely free from pus and the tenesmus had entirely disappeared.

Case IV.—Mrs. S. C. G., aged twenty-seven years, mother of four children. About two months before consulting me she had a miscarriage, and was confined to her bed about three weeks, during which time she was curetted. Directly after the operation she complained of frequent micturition and at the end of urination voided considerable blood and pus. She had consulted her regular family physician, who seemed to be unable to give her any relief, and sent her to me. On examination on June 13 I found the parts normal in appearance, except that the meatus urinarius was slightly inflamed. I catheterized her and drew off about 5 ounces of ammonical urine which contained considerable pus mixed with blood. I immediately washed out her bladder with a ½-per-cent. solution of protargol, prescribed 15 grains of helmitol, four times daily, and sent her home to bed. I called the next day and again washed out the bladder with a ½-per-cent. protargol solution and kept up the helmitol. This same procedure was repeated daily. Up to the fourth day there was no marked improvement, but on the fifth day the urine com-

menced to clear. I then increased the strength of the protargol solution to 1 per cent., and continued the helmitol. This treatment was continued for ten days more, when she came to my office. Examination showed the urine to be almost free from pus and blood. The helmitol was continued, but the irrigations stopped, and at the end of another week I discharged her cured.

Case V.—Mr. H. A. N., called at my office May 20, 1903, with the following history: Three weeks prior he had contracted gonorrhea and made a confident of one of his chums, who in turn advised him to get a patent preparation. This he had injected three times a day, and at the end of ten days the dischorge had ceased, but he noticed a peculiar dull pain over the pubes. On examination of his urine (two glass test) the first glass was very turbid, while the second was nearly as bad. He was passing urine every hour or so. His temperature was 101.2° F. I advised him to go home to bed, and prescribed 15 grains of helmitol four times a day, and ordered hot applications to be made over the pubes. On visiting him the next day I found his temperature 100.8° F.; the condition of the urine was about the same. Treatment was continued. On the following day the temperature was 99.2°; the pain had almost all gone, and the urine looked better although it still contained quite some pus. On the fourth day I washed out his bladder (glass catheter) with a 1-per-cent. solution of protargol. On the fifth day the urine was much clearer, and the bladder was washed out as before. On the sixth day the urine was entirely free from pus. Helmitol was continued, but the irrigations stopped. The patient continued taking the drug for fourteen days when his urine was normal and free from pus and has remained so.

Case VI.—E. R. L., thirty-two years old, had suffered with gonorrhea since June 3. On August 3 he complained of urinary tenesmus, and passed a very uncomfortable night, having to get up several times to urinate. On examination I found both portions of urine very turbid with traces of albumin. Helmitol, 15 grains, was prescribed four times daily. August 4, the urinary tenesmus and turbidity unchanged. August 5, urinary tenesmus not so marked, but still severe. August 6, treatment continued. Tenesmus at night about the same; urine still turbid, and of slightly acid reaction. August 7, urine slightly less turbid. August 8, urine as bad as on August 3, and on passing his water more or less pain in the urethra. August 9, urine slightly improved, and treatment kept up. August 10, urine looked better than on any day heretofore and showed no trace of albumin. August 11, patient complained of a slight chill, which, no doubt, was caused by sleeping with open window at night and a sudden rainstorm coming on. The urine was much improved, but there was a slight discharge from the urethra. Temperature normal. August 12, urine less turbid than on preceding day; urethral discharge still present. August 13, urine almost clear save for a few floating shreds. August 15, urine clear save a few shreds; slightly acid reaction. Tenesmus had entirely disappeared since the fourth day. Still a slight urethral discharge. The above treatment was continued until August 20, when the discharge had ceased entirely, the urine being perfect except a few shreds. Helmitol 15 grains four times a day was continued and I gave him some gelatin bougies containing one-half grain of protargol, to be inserted at night before retiring. This treatment was kept up until September 1, when all shreds had disappeared from the urine.

Case VII.—R. M. S., aged twenty-seven years, actor, called to see me May 5 with an acute anterior gonorrhea, this being his first experience. On examination I found the meatus highly inflamed and swollen and a very profuse discharge. He complained of an intense burning sensation in passing his urine and had very painful chordee four or five times during the day. I gave him a 1-per-cent. protargol solution to use in a hand syringe, and 15 grains of helmitol every four hours, and for the constant erections directed him to use ice cold ablutions. At his next visit, May 7, the discharge seemed to have increased more than in any of my former cases while using protargol hand injections, but I continued this treatment. The chordee was considerably better, and although the urine scalded some, this was not quite as severe as on his first visit. May 9, discharge reduced somewhat and not so thick and viscid. The burning had nearly subsided; the chordee had all disappeared. May 11, the discharge was of a seropurulent character. I increased the strength of the protargol injections to 1½-per-cent. and kept up the helmitol. May 14, the discharge was of almost watery consistency; no pain or discomfort of any kind. Treatment continued. May 18, the discharge had decreased a great deal, so I discontinued the protargol, and substituted 1½-per-cent. solution of sulphocarbolate of zinc injection. May 21, no more discharge seen since the afternoon of the day before. Helmitol was discontinued, but the zinc injection kept up. May 27, there being no discharge for nearly a week, and the patient having to fill a summer engagement out of town, I advised using the zinc injection for another week. He wrote to me two weeks later that there had been no more discharge and that he had drank beer and had seen no ill effects.

The Effect of Protoplasmic Poisons on Tryptic Digestion.—Solutions of trypsin, of a strength greater than that of .2 per cent., are according to R. Kaufmann (Hoppe-Seyler's Zeitsch., Sept. 19, 1903) not affected by the action of toluol, chloroform, thymol and sodium fluoride, extending over a period of twenty-four hours. Weaker solutions of trypsin are affected, while those of a strength of .02 per cent. or less are rendered inert. The above antiseptics act toward bacteria in the same way as they act toward ferments. This indicates that there is apparently no essential difference between fermentative and bacterial action.

CHLOROFORM IN LABOR.*

BY EDWIN RICKETTS, M.D.,
OF CINCINNATI.

Shakespeare expressed it well in saying,

"Not poppy, nor mandragora,
Nor all the drowsy syrups of the world,
Shall ever medicine thee to such sweet sleep."

Normal labors are surgical procedures, and should be so considered from the beginning of the first stage until convalescence has been well established. The importance of carrying out the strictest phophylactic measures on diet, catharsis and cleanliness is better understood and more fully appreciated. The importance of the conservation of maternal force during the puerperal state—and especially during delivery—has not been sufficiently emphasized.

Chloroform, during the latter, is the remedy that is faithfully to conserve the energy of your patient. This truly surgical process—labor—that is traumatically imposed, is the only one of the list that has been shorn of its dignity. This comes from its frequency, and for the low ebb of midwife commercialism that is indulged in by too many physicians that are doing a good amount of obstetrical work. We have too many would-be first-class obstetricians who advise to "let nature take its course," getting in in time to order the cord tied, cut and dressed. If the patient goes along all right, with him it is well enough; but if she does not, and recovers after a siege of sepsis, or goes down to death, he is content to try and excuse himself on the ground of dispensation of Providence. It is not for the cases that have made sheer recoveries that he should be praised, but it is for the death list, and the list of slow and tedious recoveries that he should be criticized.

These are the chaps in medicine that antagonize the administration of chloroform in labor; always trying to show the extreme danger in the use of the drug. The teachings of the modern text-books on obstetrics is rather against the use of chloroform in labor. The results of those that have long used it, and the statistics recently given by J. C. Reeves, of Dayton, Ohio (but one authentic death); goes to prove that this is unwise teaching, even to undergraduates and young practitioners. Lacerations following childbirth, along with contusions of the urinary bladder, uterine and vaginal walls, pelvic floor—too often ending in sepsis and pus—are far more *frequent following* so-called *normal labors* than are those who have been carefully delivered under chloroform.

For the reason that the Hyderabad and similar commissions have not settled some scientific points as to the modus operandi of the drug is no contraindication for its use. It conserves her strength; it annihilates that pain that none but the parturient woman can intelligently describe. It does not increase the risk of post-partum hemorrhage. It lessens the risks of the soft tissues being lacerated. It does not add to fetal mortality. The Biblical objections are myths, and they are answered by another which says, "Adam was put into a deep sleep before the rib was removed for the making of the first woman." Today, as then, man is the first to demand prompt relief from trivial pain, and the first objector for any extended anesthesia to women in labor.

Chloroform was first used in Edinburgh in 1847 by Sir Jas. Y. Simpson. He says it should be used "to diminish and annul the physical pains that accompany the passage of the child's head through the pelvic cavity and outlets." That the reputed failures and misadventures are attributable to two causes. First, impurity; second, in not giving it in *sufficiently large* and *rapid doses.* He says, "For operative purposes in midwifery, the anesthetic state should be as complete and profound as when it is induced for operative purposes in surgery." After the first full dose, a few inhalations before or with each returning uterine contraction are generally sufficient. The state of anesthesia should be made more deep as the head passes the perineum and vulva. His rules were: (1) Begin the inhalation of chloroform when the patient *complains* of *much pain.* This is generally toward the end of the first stage. (2) *Always inculcate perfect quietness around the patient, particularly when commencing to give the chloroform.* (3) Only give it during the pains, and withdraw it during the intervals.

Exceptions.—Give a whiff of the chloroform also during the intervals when the pains are very severe, and the patient continues complaining of them. Give small doses, or only repeat them every second or third pain when the chloroform affects the action of the heart and uterus. *These cases are very rare.*

(4) When given during this stage, the anesthesia need not be deep, unless the suffering be great or the system of anesthesia disagreeable. (5) As the second stage progresses make the anesthesia so complete as to destroy all sensibility. (6) Do not allow the urinary bladder to become overdistended. (7) *Do not restrain the patient to one position.* (8) Be sure to remove the chloroform as soon as the child is born. (9) Do not awake the patient artificially.

Notwithstanding these rules were laid down by Simpson fifty-six years ago—who was the first to administer chloroform in labor and its first and greatest champion—chloroform in labor has been sadly neglected, and without cause. As Simpson says, if the patient suffers, relieve her; no matter what stage of labor she is in. If the pain is continuous, the chloroform should be administered to the point of relief, which should be maintained.

The exhausted pregnant uterus for its unsuccessful efforts at delivery in a prolonged labor may be the cause of post-partum hemorrhage. After this exhaustion, with the delivery to be completed under chloroform, after the head has been resting on the perineum for hours, and for

* Read before the Cincinnati Academy of Medicine.

any post-partum hemorrhage, the remedy has been accredited as the cause. Abdominal surgery has thrown much convincing evidence on this point. Many cases in which the abdomen has been opened for the removal of a fibroid, a cystoma, or appendix—at the fourth, fifth, sixth, seventh or eighth month, under surgical anesthesia the *strong uterine contractions have been observed* by *operator* and *assistants*. Recovery of these *patients takes place* and *with no precipitation of labor for the administration of chloroform*.

Impurity and expense of chloroform is hardly to be considered at this day, for the reason that we have many reliable manufacturing firms putting out the drug in its purest form, and at reasonable prices.

Simpson says that no special kind of inhaler or instrument is necessary for its exhibition. "A little of the liquid diffused upon the interior of a hollow-shaped sponge, or a pocket handkerchief, or a piece of linen, or paper, and held over the mouth and nostrils so as to be fully inhaled, generally suffices in about a minute or two to produce the desired effect.

Whatever may be used for holding the chloroform, it should never be allowed to rest on the patient's face. It should be held in the hand and the anesthetic frequently replenished on the inner surface in five to ten-drop lots of the drug, and held to the side of the patient's face so that none of the chloroform can come in contact with the eyes. With this frequent exposure of the patient's face, you can better regulate the intelligent administration of the drug. Before beginning the administration of the drug, observe the rule of Simpson of *exacting quietude;* gaining the confidence of the patient by assuring her that all is to go well. Never force the drug on to any patient. Show and explain to her how to breathe it in slowly, until she is accustomed to the odor, and especially as to its early effects. Assure her from time to time that she is to be relieved of the pain. Is not to know when the child is born, but that she is to be able *to reply to any questions that you must be sure to ask*. This is to reassure her more than anything else you can say. Do not be in a hurry to begin. It must be quietly, having the patient begin by inhaling in a shallow manner (never beginning by deep inhalation) accustoming the taste, smell and effects to the patient. Tongue forceps are an abomination; while the annointing of the face is an unnecessary inconvenience, and in both instances are alarming to the patient—things to be positively avoided. Deep inspiration is seldom necessary with the proper management of the case; neither is the previous administration of morphine or whisky necessary.

The covering of the face with a napkin or handkerchief on which is dropped the chloroform is to be avoided, for the reason that the face should not be continuously obscured from the physician.

Fold the napkin or handkerchief, holding the same in the hollow of the left hand. In taking the hand from over the nostrils and mouth—for the dropping of the chloroform on the cloth—the patient is sure of alternating intervals of inhalations *of air alone to be followed by chloroform admixed with air*. With the cloth in the hand, the facial expression with its color, pupils, breathing, temperature of the nose, ears and face are easily and more intelligently kept under observation. The pulse and respiration are to be intelligently observed.

Pulmonary tuberculosis, *with any of the heart lesions, diabetes or albuminuria are not contraindications for the use of chloroform*. In some instances it has proven a prophylactic remedy of no mean degree in puerperal convulsions.

The tendency of the day is toward numerous complicated anesthetic outfits for the administration of chloroform, but the simple rules, with the simpler means, as suggested by Simpson, have not been improved upon.

In the administration of chloroform in labor the tendency is to use from four to six times as much as is necessary. The same criticism stands good in the general use of chloroform. In quite an extensive use of chloroform in labor, I have never found it necessary to resort to any of the cardiac or general stimulants. On the other hand, I have seen a weak pulse grow strong by its use; a chaotic condition of the household changed to quietness and confidence for the artificially induced sleep. For this there was

> "No danger in what show of death it made,
> More than the locking up the spirits a time,
> To be more fresh for the reviving."

MEDICAL PROGRESS.

MEDICINE.

Internal Administration of Tuberculous Antitoxin.—The internal administration of various antitoxins has been tried at various times with more or less success. Roncagliolo claims to have increased the antitoxic power of the serum of the patients which he treated by this means and moreover noticed an encouraging therapeutic effect. F. Figari (Berl. klin. Woch., Jan. 18, 1904) has lately made some investigations for the purpose of determining whether the component parts of the blood of animals immunized against tuberculosis contained antitoxic substances and whether these, when administered internally, would afford a resistance against tuberculous toxins. Before and after the experiment he determined the agglutinating powers of the sera and their resisting powers against a lethal dose of tuberculin. The difficulty of providing fresh material was overcome by drying the blood of immunized animals and then reducing it to powder form. The experimental animals were guinea-pigs, to which he gave three grams of this powder daily, mixed with their food. The results obtained were as follows: The sera, after twenty-five days, manifested an agglutinating power of 1:5 in twenty-four hours. After fifty-four days of treatment, the relation was 1:12; and in eighty-five days, 1:25. In the latter instance the agglutination was 1:10 even after six hours. No

agglutinating phenomena were present in the sera of any of these animals previously. The antitoxic relations were as follows: After eighty-five days a lethal dose of tuberculin was injected into all the animals. About one-half remained alive for thirty-six hours, while the control animals died after twelve to sixteen hours. The remaining animals all survived the injection. The powder was also given to one of the author's patients. For eighty days he was given four grams daily with a noticeable improvement at the end of that time. The gain in weight amounted to almost 12 pounds, and the agglutinating power of the serum rose from 1:10 to 1:50. These experiments will be continued.

Etiology of Gout and Its Treatment.—The uric acid diathesis has long been considered to play an important rôle in the production of gout. Numerous authors have described an accompanying form of dyspepsia, and Falkenstein (Berl. klin. Woch., Jan. 18, 1904), as the result of these observations and his own, that the cause of gout must be sought in the stomach and that a diseased process involves the glands of the fundus which secrete hydrochloric acid. The main point in his method of treatment is the administration in large doses of hydrochloric acid, from 10 to 20 drops in two glasses of carbonated water three times daily. For the acute attacks he prefers aspirin, as it does not interfere with free perspiration. Opium is not recommended as it inhibits secretion. Colchicum he believes of comparatively little value, as it merely alleviates the attack without affecting the retention of the uric acid. The alkaline waters are also contraindicated, as they neutralize the free hydrochloric acid in the stomach, which is already diminished in amount. As for thermal treatment, he has always found dry heat of greater value in local applications than moist, and ice is apt to exert a harmful influence. Sugar is entirely contraindicated; the diet should be moderate and exclude nucleic substances. Alcohol is also contraindicated. The main point made by the author is the administration in all cases of sufficiently large amounts of hydrochloric acid.

SURGERY.

Diagnosis and Treatment of Intussusception.—Acute intussusception is the most common variety of intestinal obstruction in infants and forms about one-third of all cases of acute obstruction. H. Roth (Med. Rec., Dec. 19, 1903) has reviewed the literature upon the subject and reports four cases which have recently come under his care. The importance of an early diagnosis is urged, and since the symptoms associated with this disease are usually characteristic there ought to be few failures in recognizing it. The disease usually begins suddenly and, as a rule, in children in previously healthy condition. The first and most important symptom is pain. This is usually paroxysmal and colicky in nature. Soon after the appearance of pain, vomiting occurs at first at long and later at shorter intervals, and may become projectile in character. With the onset of pain a marked change in the appearance of the child will be noticed. It rapidly passes into a condition of shock with anxious expression of the face, pale skin, rapid and feeble pulse, the skin may be covered by cold perspiration and the respirations may be shallow. This appearance of illness is of great diagnostic value for the child, which a few hours before was in perfect health. Several hours later there may be a discharge of bloody mucus, but this may not appear till the finger is inserted and withdrawn. Tenesmus may occur later, especially when the tip of the intussusception can be felt per rectum. In the early part of the disease there is no rigidity of the abdominal wall, and during the paroxysms of pain we may feel a tumor or fulness, especially in the right iliac fossa. If the case is allowed to proceed the picture soon changes by the addition of symptoms referable to the gangrene and peritoneal sepsis which rapidly appear. It is important, therefore, that the diagnosis should be made at an early hour and treatment instituted. The treatment of the disease in former years was principally mechanical, by injections and inflation. The mortality from this method was about 75 per cent. During recent years operative treatment has come more into vogue, and with early surgical interference the recoveries have greatly increased. All authorities are now agreed that the condition should be likened unto a strangulated hernia and that mechanical means of relief should not be persisted in, but that a laparotomy should always be done within the first few hours. Before mechanical means are attempted, furthermore, the patient should be prepared for operation and anesthetized so that surgical interference may at once proceed, if other methods fail.

Excision of Tuberculous Mass from Liver.—Cases in which portions of the great abdominal viscera are cut away possess a great deal of interest, partly because of the difficulty of the operation and of the importance of the technic. This case, reported by Robert M. Rome (Ann. of Surg., Jan., 1904), is briefly outlined as follows: Patient was a woman, forty-two years old, who had never been seriously sick but who had been "bilious" all her life. The family history was good, save that her mother had suffered from some obscure liver trouble. In the middle of August, 1902, she was suddenly seized with severe pain in the right lumbar region which lasted twenty-four hours, after which it decreased in violence, but the part remained tender. She was obliged, although able to get about, to favor the right side, because of a pulling pain there, and she was unable to sleep or rest upon that side. When walking, she bent somewhat to the right and stooped forward. Six weeks after the onset, she was operated upon; an incision being made over the site of a slight tumor which had developed at a point midway between the cartilage of the tenth rib and the crest of the ilium. The intestines were adherent to the liver, and after these organs had been separated, a tumor in the right lower lobe adherent to the parietal peritoneum was probable. It was apparent that it could be removed by cuneate section. The sutures were introduced half an inch apart and half an inch from the margin of the triangle. After a number had been inserted, the wedge containing the growth was cut away with scissors. The tumor removed was about the size of a goose egg and, despite the considerable area excised, a speedy tying of these sutures satisfactorily stopped all hemorrhage. The abdominal incision was closed without drainage. A microscopical investigation revealed a typical tubercle. Dr. Keen, in reviewing the surgical conditions of the liver, mentions (1) herniated left lobe, 5 cases; (2) syphiloma, 12 cases; (3) carcinoma, 17 cases; (4) angiofibroma, 1 case; (5) cavernoma, 1 case; (6) endothelioma, 1 case; (7) angioma, 4 cases; (8) adenoma, 7 cases; (9) sarcoma, 5 cases; (10) cystoma, 1 case; (11) small calculi, 1 case; (12) hydatid cysts, 20 cases. It is thus seen that the case above reported adds another tumor to Keen's list.

Pathology and Treatment of Recent Fractures of the Patella.—So much has been said for and against the operative treatment of this frequent condition that a résumé of the present status of the literature is of interest. S. C. Plummer (Ann. of Surg., Jan., 1904) believes the following to be a fair statement of the present status of the question: (1) Operative treatment

should never be undertaken except under the best aseptic conditions; (2) presupposing these to exist, not every case should be subjected to operation, but only those in healthy patients of suitable age with at least half an inch of separation of the fragments and lateral tears which compromise the "reserve" extension apparatus, or in patients following arduous occupations; (3) the operative treatment fulfils all the indications for treatment in a manner which the non-operative method can only partially receive, but good functional results follow the non-operative treatment as a rule; (4) early massage in all cases favors the early and complete restoration of function of the joint and should be used in all cases; (5) if operative treatment is employed, the open arthrotomy should be used; (6) absorbable suture material applied to the soft parts is sufficient in nearly every case.

Demonstration of the McGraw Ligature.—A great deal has been written about this method of intestinal technic. It was devised by Theodore McGraw twelve years ago, but was not extensively used until very recently, because of the popularity of the Murphy button. Continued reports, however, from all over the world, show that this popular mechanical device is not without very grave disqualifying objections. A. J. Ochsner (Ann. of Surg., January, 1904) reports a series of 40 cases of gastro-enterostomy in which he made use of the elastic ligature. The effect on the patient was no greater than that following the use of the Murphy button. In all these cases there had been no peritonitis. Three had died, one two weeks after the operation from exhaustion, another in three weeks and another in six weeks. So simple is the technic of this ligature that he had recently used it in all cases in which there appeared to be even the slightest pyloric obstruction. Theoretically, Ochsner believes that all mechanical means must ultimately be abandoned and that surgeons must do all of these operations with the needle and thread. Practically, however, he had tried nothing which had been as satisfactory for creating gastro-enterostomy or entero-enterostomy in suitable cases as this method of elastic ligature.

Treatment of Typhoid Perforation.—This much-dreaded complication, which has a mortality rate of over 99.9 per cent., according to accredited authorities, is being gradually stripped of its deadliness through surgical intervention. R. G. Le Conte (Ann. of Surg., Jan., 1904) reports three consecutive successful cases operated upon during the last month at the Pennsylvania Hospital. In the first two the recovery was permanent, in the third, recovery from the primary perforation was assured by operation, but the patient died ten days later from a secondary perforation. Since the symptoms indicative of perforation are as yet by no means understood, a close review of these cases must be of great value. In general the histories were as follows: *Case I.*—Male. Russian Jew, thirty-eight years old, suffering from an attack of moderate severity; temperature on admission 102.2° F. Twelve days after admission, during which time the case had presented no symptoms of an unusual character, temperature touched normal. Convalescence was uninterrupted, and he left the hospital fifty-six days after the onset of the attack. He was readmitted to the medical ward under the care of Dr. Stengel three weeks later. The temperature was 103.3° F., pulse 112, respiration 38, tongue coated white, edges and tip red, very tremulous, a few râles posteriorly on the right side of the chest, spleen enlarged and tender. Abdomen rounded, soft, flabby, slightly tender; rose spots; urine, slight trace of albumin, hyaline and granular casts. Widal test not positive. It was a clear case of recurrence. On the eighth day after admission he complained of pain in the abdomen, which for twelve hours was not severe. At about the tenth hour of pain, the temperature was 101.2° F., four hours later it had fallen to 97.8° F., pulse 100; an hour and a half later there was profuse sweating with shallow respiration and anxious expression. At that time temperature was 97.6° F., pulse 140, respiration 40; abdomen tympanitic, rigid and tender, especially on the right side. Three hours later, under ether, a three-inch incision was made in the right semilunar line below the umbilicus. This was three hours and a half after the first evidence of collapse, six hours and a half after the onset of severe pain and 17 hours from the first pain noticed. Some cloudy non-odorous fluid escaped. The cecum was brought out and eight inches up the ileum a large inflamed Peyer's patch was found with a small perforation in the center. The pelvis was thrown downward by tilting of the table, and the pelvic and peritoneal cavity irrigated with salt solution. It was mopped dry, rubber drainage inserted and five wicks of gauze run between the coils. Temperature after operation, 98.2° F., pulse 128, respiration 40. The temperature reached normal eight days after operation, and convalescence was uninterrupted. *Case II.*—The Widal test was positive. On the sixteenth day immediately after a bath, he complained of sharp pain in the right side. There was no vomiting. Leucocytosis, 9,600; pain and tenderness increased. An hour later temperature 100° F., pulse 110, respiration 24. Five hours after onset of pain he was operated upon. One foot from the cecum a large necrotic ulcer was seen with pin-head sized perforation; no attempt at walling off was seen. The hole was inverted. A wet toilet of the peritoneum was done; the reaction and subsequent convalescence was normal. Both these cases, in the opinion of the author, probably owed their recovery to the fact that the symptoms they presented were of an almost classic character. In neither case was any attempt evidenced of an effort to "wall off." In both cases the perforated area seemed to be in contact with the parietal peritoneum. This is much more sensitive than the visceral sheet and may be the reason why some cases present practical symptoms while others do not. The presence of omentum covering the perforation might in itself be sufficient to delay the advent of symptoms for a fatal period.

Removal of the Prostate and of the Prostatic Urethra for Senile Enlargement.—In this country the perineal route has been brought to such a stage of perfection that it is of particular interest to note what a representative operator of England has to say upon the suprapubic operation. B. G. A. Moynihan (Ann. of Surg., Jan., 1904) records the history of 12 cases and details the technic which took birth virtually in an operative accident. While shelling out the prostate of a case some two years ago, he unintentionally removed the entire gland together with the prostatic urethra. He was naturally alarmed at the prospect before the man, but to his surprise convalescence and recovery of function were complete. The technic is as follows: The bladder is washed out with one per cent. carbolic acid and filled with ten or twelve ounces of the same solution. A rubber glove is worn on the right hand, so that after the rectal manipulations the removal of the glove will leave a clean hand. The bladder is opened above the pubes. Its walls are then made fast by a heavy silk ligature to the abdominal incision. This prevents tearing of the viscus. These are left for three days. The trigone is then incised immediately behind the internal meatus. The prostate is then steadied with the right finger in the rectum, the larger the organ the easier the stripping. The mucous membrane is torn

freely. The anterior portion of the prostatic urethra at its junction with the membranous portion is torn through after the prostate is elsewhere entirely free. A catheter is passed and the bladder is freely flushed with hot salt solution. On the fourth day and on each day thereafter a catheter is passed, and the bladder washed. On the seventh day the catheter is tied in place. If the patient be feeble and old, it is desirable to allow him to get up before the end of the first week. The urine ceases to pass through the wound about the twentieth day. In about a month patient is usually passing urine spontaneously at natural intervals without discomfort or difficulty. Occasionally, where the cystitis was extremely severe and the urine foul, after the irrigation of the bladder, a stream of oxygen was passed through the cavity, the suprapubic wound having been capped with an impervious cover which allowed but a small leakage of the gas. In this way, the whole cavity was thoroughly oxyginated and distended, and healing was certainly hastened. Of the 12 cases operated upon, one died.

Amputation at the Hip-joint for Sarcoma of the Femur.—The question of the curability of this condition by operation is one that is still more or less unsettled. From personal observation, W. B. Coley (Am. Med., Jan. 9, 1904) believes that sarcoma in this locality represents one of the most malignant forms of tumor with which we have to deal. He reports five cases of sarcoma of the femur treated by hip-joint amputation, of which two died within a year, one lived two years, one was not traced, and the last, a recent case, is the only one known to be alive. Of four patients treated by amputation just below the trochanter, one with sarcoma of the femur died four months afterward of lung metastases, the second had a local recurrence at the end of fifteen months, and after disarticulation had been done, lived two years longer; the third, with melanotic sarcoma of the skin of the thigh, died four months later of general involvement; the fourth, a recurrence in the thigh after primary sarcoma in the tarsus, is well six years after the operation. The author believes that hip-joint amputation is to be preferred to resection or to amputation through the shaft. Recurrence being almost the invariable rule after all methods of treatment, a thorough course of mixed toxine treatment after operation, as a prophylactic measure, offers the best hope of a permanent cure.

Obstruction of the Large Gut.—Definite obstructions, due to adhesions which arise from the chronic irritation of inspissated feces, are a very prolific source of augmenting the constipated condition. W. Arbuthnot Lane (Lancet, Jan. 2, 1904) states that he discovered the existence of this condition accidentally while operating upon cases of supposed nephrolithiasis. The relief of the pain and the constipation in these cases were evidently due to the extensive separation of the colon from the kidney. When fecal matter accumulates in the intestines, there are two portions which are particularly likely to become inflamed. These are the cecum and ascending colon and the sigmoid. In consequence of this irritation the walls become inflamed to a small degree and peritoneal adhesions form between it and the abdominal wall. These adhesions oppose the downward and inward displacement of the loaded cecum. Gradually they thicken and in time suffice to support the overloaded bowel in the erect position. The adhesions which bind down the cecum externally also fix the proximal portion of the appendix. This may very often lead to attacks of appendicitis. The formation of adhesions between the cecum not alone supports the overloaded organ but also prevents its displacement upward and inward and the formation of volvulus. In spite of the thorough division of such bands of adhesion and the complete liberation of the gut, a large percentage of cases will recur. It being probable that the injury arising from pain and autoinfection from decomposition does greater harm to the individual than any good he may derive from absorption of foodstuffs from the part, Lane determined to exclude the greater part of the large bowel from the intestinal path. He therefore connected the ileum with the cecum by making a very free lateral anastomosis between the lower limit of the ileum and the upper part of the rectum, or the sigmoid, if the latter were not accessible. The results of such treatment have been very satisfactory, the pain and tenderness having disappeared, the cachexia and inactivity resulting from the absorption of ptomains having likewise passed away. The only objection to lateral anastomosis is that the presence of any large quantity of solid fecal matter near the opening in the large bowel may cause feces to pass on into the cecum. As a guard against this, he now divided the ileum closing its distal aperture, making its proximal section open into the lower end of the large bowel, thus rendering it impossible for any material to enter the cecum.

Hour-glass Stomach.—Hour-glass stomach may arise from three separate causes—chronic gastric ulcer, perigastritis due to adhesions, and cancer. The deformity in itself constitutes a distinct disease, which is associated with a peculiar train of symptoms. A. W. Mayo Robson (Lancet, Jan. 2, 1904) states that the name "hour-glass stomach" was adopted long ago when the disease was thought always to be congenital and before it was recognized that the stomach might be divided into more than two cavities. He cites 23 cases which at operation all showed distinctively that hour-glass stomach owes its origin to definite organic disease. Doubtless very rarely it may exist as a congenital malformation, just as narrowings may be found at the pylorus, in the intestine or in the rectum. In an experience of over 1,000 operations on the upper abdomen, however, in which the stomach was seen and examined, and of about 400 which have been executed directly upon the stomach itself, he has not met with a single case of congenital hour-glass constriction. The symptoms for a time depend entirely on the cause, whether that be ulcer, cancer or perigastritis, but ultimately, when the deformity has developed, the signs are more or less distinct. The cause can usually be diagnosed without much difficulty, and in the majority of cases the effect can be as positively proven. One of the most characteristic signs of hour-glass stomach is the following: If the stomach has been washed out until the returning fluid is absolutely clear, there flows suddenly from the tube a foul stream of material, the supposition of hour-glass stomach is pretty definitely substantiated. Wolfer showed that on washing out the stomach the fluid might entirely disappear, it having passed through the second pouch. The distinctiveness of the symptoms naturally depends upon the position of the contraction. In the greater number of the cases cited, the constriction was located four inches from the pylorus, and in nearly all the cases the proximal cavity has been larger, giving rise to the well-known symptoms of dilatation of the stomach due to pyloric stenosis. Frequently the second cavity is of minor importance, and in such cases the condition is usually not diagnosed, the operation being undertaken simply for relief of the dilatation and the ulcer. The treatment of the condition must be purely surgical, and the technic cannot be decided upon until after the abdomen is opened. When the stricture is centrally located, gastroplasty is the most desirable procedure. This occasionally may be compounded with pyloroplasty. Gas-

troplasty may be performed either by means of simple sutures or by suturing over the largest size bone button, the important point being to make a sufficiently large opening. Dr. Jos. A. Blake has recently suggested a modification of gastrogastrotomy after the method employed by Finney in pyloroplasty. The technic served well in one case. It is of the utmost importance that drainage be perfect. In two cases of carcinoma in which the stomach was removed almost in toto, one case lived for sixteen months and the other is still progressing favorably, although the operation was done three years ago. Of the 23 cases cited, 19 were simple and 4 were malignant. Of the simple cases, 11 were operated upon by gastroplasty alone and all the patients recovered.

An Improved Hemostatic Bandage.—As far back as the sixteenth century, this matter was receiving attention. Ambrose Pare is accredited with having devised the bandage recently popularized by Esmarch. Siegfried Spiegel (Zentralbl. f. Chir., Dec. 26, 1903) describes an ingenious apparatus by which the amount of pressure exercised upon the extremity can be definitely measured. This, however, is not its only advantage. It is well known that with the average elastic roller bandage, the method of liberation is extremely irregular, the pressure usually being taken off with a snap which places an undesirable and sudden pressure upon the recently ligated vessels. In this apparatus the bandage passes around the extremity but once and the pressure is relieved by a thumbscrew. The material of which it is made is not elastic. In the latter class of bandages there are only two conditions possible—either the blood is entirely shut off, or it is turned loose with a rush. The new instrument is shown in an excellent engraving.

Anastomosis for the Vas Deferens.—Suture of this important duct is of great interest. A successful case is reported by J. L. Thomas (Brit. Med. Jour., Jan. 2, 1904). The case was one of bilateral severance of the vas by a knife. An oblique incision was made over the course of the inguinal canal, and the two severed ends which were found to be separated about half an inch, were brought together. The testicular end of the vas was cut obliquely by means of a cataract knife. The urethral end was split longitudinally for one inch. This free end was further divided for about half an inch from its extremity so as to provide two tails of equal size. Each tail consisted of one-half of the longitudinally split vas deferens. The obliquely cut free end of the testicular portion of the vas was placed with its lumen in contact with that of the testicular portion, and was fixed by means of fine, silk sutures as closely applied as possible. The two tails were then enveloped around the testicular portion and sutured. Layers of fascia were subsequently wrapped around the anastomosed vas and fixed with sutures. The practicability of the above method of anastomosis can be demonstrated on the cadaver by injecting fluid along its lumen when it will be found that the joint is tight. This procedure is easier of application than end to end anastomosis or any form of implantation, and is a valuable step forward in conservative surgery. The article is well illustrated by diagrams.

PHYSIOLOGY.

Observations on the Functions of the Spleen.—In the normal animal, according to T. Lewis (Jour. of Anat. and Physiol., Jan. 1904), the function of hemolysis is carried on by the spleen, but chiefly by other members of the hemolymph series of organs. There is a proliferation of leucocytes in all glands of the series, and a limited destruction of the same in hemal and hemal lymphatic glands. In the latter there is also a destruction of polymorphonuclear cells and coarsely granular eosinophiles. The processes are not widespread. A disintegration of erythrocytes outside the phagocytes takes place, in all probability by a ferment action. Appearances are seen which suggest the view of ingestion by leucocytes of the disintegrated particles of erythrocytes, with the formation of coarsely granular eosinophile cells. There is evidence that all the leucocytes are derived from lymphocytes, and that phagocytes have their origin in hemolymph organs, from the endothelial cells lining the sinuses, capsule, trabeculæ and reticulum.

The Rapidity of the Nervous Impulse in Tall and Short Individuals.—The question as to whether the stature of the individual and the corresponding difference in the length of homologous nerves has or has not any influence on the rapidity of the transmission of the nervous impulse, has been decided by N. H. Alcock (Proc. of the Royal Soc., Dec. 19, 1903), who finds that per unit length, the rate of the nervous impulse is the same in all individuals examined. It takes longer, therefore, for the nerve impulse to traverse the limb nerves in a tall man than in a short one. The difference is .001 second approximately. It is also found that the nodes of Ranvier exercise no influence on the rate of impulse.

The Fat-assimilating Function of the Human Placenta.—It has been proved, according to J. Hofbauer (Hoppe-Seyler's Zeitsch., Sept. 19, 1903) that the nutrition and growth of the embryo are not dependent only on the processes of diffusion through the placenta. Harvey was the first to consider the placenta a digestive organ. Histological investigations enable the author to conclude that with respect to the absorption of fat, the villi of the chorionic membrane, both in the structure and distribution of their element, bear many resemblances to corresponding structures in the mucous membrane of the intestine. The uses of the fat thus assimilated by the placenta may, in the embryo, be manifold. Thus it may build up the fatty tissue as such, may serve in the formation of numerous other tissue elements, and by its own oxidation, may spare the consumption of the proteids.

Chemistry of Blood-Coagulation.—A few new facts concerning the complicated process of blood-coagulation have been discovered by I. Morawitz (Deutsch. Arch. f. klin. Med., Vol. 79, No. 1 and 2). It appears that the fibrin-ferment necessary for clotting, results from the interaction of three substances: a calcium salt, thrombogen, and thrombokinase. The latter itself behaves in many ways like a ferment, since heat and putrefaction destroy it rapidly, and since non-dialyzable and precipitated by alcohol. Thrombogen occurs only in blood and lymph, but thrombokinase can be obtained from all organs. In the circulating plasma neither one of these substances is present in solution; they are only set free after the blood has left the vessels and the thrombogen appears first. During normal clotting only part of the thrombogen is rendered active, hence even the serum contains this substance, which will become active in the presence of kinase and lime.

Influence of Blood-pressure on Blood Composition.—The exhange of fluids between blood and tissues occurs in the capillary system. Here the fluid leaves the vessels, circulates in the interstices as lymph and then is absorbed directly into the venous radicals or enters the veins indirectly through the lymphatics. Increasing or diminishing the blood-pressure will have a decided influence upon this exchange of fluids, as can be seen by comparing the concentration of arterial and venous blood after injections of suprarenin and chloralhydrate. The number of red blood cells in normal, arterial and venous blood is about the same, but when O. Hess (Deutsch. Arch. f. klin. Med., Vol. 79,

Nos. 1 and 2) injected suprarenin into the femoral artery of a dog, the venous blood contained up to 25 per cent. more erythrocytes, while after chloralhydrate there was a decrease to the same degree which can be traced as far as the right heart. The hemoglobin shows the same variations. The fact that arterial blood always remains the same, points to a regulating mechanism within the body which is to be found in the lungs. The softness and elasticity of the tissues of this organ, the distribution of the capillaries and the abundance of lymphatics permit of an absorption of lymph in the case of increased arterial pressure and a secretion of plasma where the pressure is subnormal. The lungs are eminently fitted for this function since the vascular tonus here is independent of that of the systemic blood-vessels. The liver probably also assists in making up the loss of fluid. The variations are only noticed after considerable changes in pressure of short duration; where the blood-pressure is affected over a long period, the entire vascular system will gradually adapt itself so that differences between arterial and venous blood are no longer noticed. After venesection, the regulating mechanism apparently fails, for a diminution of red cells occurs in both arterial and venous systems.

THERAPEUTICS.

Relations between Physiological Action and Chemical Constitution.—A careful study of the relationship between the chemical constitution of phenol and its derivatives, and the effects produced by their action upon the nervous system, has been made by S. Baglioni (Zeitsch. f. Allg. Physiol., Vol. 3, No. 3). He divides these substances up into four groups with their effects, as follows: (1) The ability of phenol to produce clonic convulsions and to increase the excitability of the motor mechanisms of the spinal cord, is also possessed by its salts (phenolnatrium), its homologues (α- and β-cresol), the bivalent and trivalent phenols (pyrocatechin, resorcin, hydrochinon, pyrogallol, phloroglucin), and the naphthols. They all have a benzol-nucleus, or two condensed benzol nuclei, to which are bound from one to three hydroxyl groups, with or without the addition of oxygen. The addition of oxygen or hydroxyl groups reduces the activity; thus: phloroglucin and pyrogallol act only in larger doses. All these substances possess in common the property of producing paralysis when administered in large doses. The addition of a member of the coal-gas series (CH_3) does not diminish the capacity to produce clonic convulsions (cresol), but the presence of several members of this series (CH_3 and C_3H_7) inhibits it entirely (thymol), and in this case there appears only central paralysis, which is to be attributed to the methyl and propyl derivatives. (2) In the second group are substances closely related to the first, consisting of benzol toluol, xylol, anilin, anisol, phenetol, guaiacol and veratrol. The first manifestation of their activity is not excitation but paralysis, which last for a longer or a shorter time, to be followed by clonic convulsions. Of these substances, benzol, toluol, xylol and perhaps also anilin have this in common, namely, the paralysis is not complete, they have in their benzol nucleus no hydroxyl group and have many chemical likenesses among them. Since it has been shown that in the organism benzol is oxidized into phenol, the hypothesis is suggested that this group can elicit clonic convulsions only when a hydrogen atom of its benzol-ring is oxidized into a hydroxyl group. Anisol, phenetol, guaiacol and veratrol have these characteristics in common: the paralysis is profound and of long duration; they are all esters of phenol or pyrocatechin, and they are made up of a phenol (or pyrocatechin) remnant and a methyl alcohol (or ethyl alcohol) remnant. The more distinct paralytic effect is thus understood, since alcohol is a marked narcotic, and the paralysis increases *pari passu* with the addition of alcohol groups. (3) The third group related to phenol are happily characterized by the fact that they elicit paralytic phenomena in the nervous system. They have completely lost the property of producing clonic convulsions. To this group belong chiefly acetanilid, phenylhydrazin, benzylalcohol, benzylaldehyde, acetophone, benzoic acid and salicylic acid. They produce paralytic effects of varying degree, and may be differentiated by means of various characteristics. In the first division of this group belong benzyl-alcohol, benzaldehyde, acetophenone, and benzoic acid. They are all built up from a benzol-nucleus, to which a methyl side-chain is attached. This side-chain is not easily split from the benzol nucleus, but it is easily oxidized to CO_2H, the more oxygen present in the side-chain, the less is the paralytic effect. Thus benzyl-alcohol is a powerful depressant, while still less so is benzaldehyde and next benzoic acid. From these facts one can infer that the narcotic power depends upon the ability to draw oxygen out of the biogen molecules of the nerve-centers, hence upon the power of reduction possessed by these substances. It is well known that benzyl-alcohol and benzaldehyde are oxidized in the body into benzoic acid. (4) The fourth group is made up of the aromatic compounds, which the author has proved to be inert with respect to the central nervous system. Here belong nitrobenzol, tyrosin, hippuric acid, gallic acid, benzidin and pyridin. In this group it is seen that the entrance of CO_2H into the benzol ring inhibits the capacity to produce clonic convulsions, whether the CO_2H is bound directly (gallic acid) or indirectly (tyrosin, hippuric acid). NO_2 is also capable of doing this (nitrobenzol). If the benzol ring is changed by the substitution of an N for CH, physiological action is abolished (pyridin).

Treatment of Gastric Ulcer.—It has been customary to keep patients on a milk diet at least four weeks after a hemorrhage from a gastric ulcer and to avoid all other, especially proteid foods. This, M. Wagner (Münch. med. Woch., Jan. 5, 1904) thinks, is a mistake. He has often observed the good effects of proteids in the hyperacidity of chlorotic girls, without ulcer and was led to try the same diet in ulcer, arguing that albumin binds the free hydrochloric acid, which keeps up the irritation better than any other food. The patients are often in a condition of chronic inanition; to begin with rectal enemata and small amounts of milk would be to keep up the starvation and thus to prolong the healing of the ulcer, while large quantities of milk, sufficient to meet the demands of the system, would be risky. The treatment, as practised by the author, is as follows: Absolute rest for at least four weeks, ice-bag to the epigastrium. On the day of hemorrhage, 200 to 300 c.cm. of iced milk and 1 to 3 fresh raw eggs are given, together with two grams of bismuth three times a day. By the end of the first week, the milk has been increased to 800 c.cm. and the eggs to six to eight a day. Raw, scraped meat is allowed after the sixth day and after two weeks boiled rice or farina and zwieback. In three to four weeks a carefully selected mixed diet is well borne. The amount of bismuth is reduced considerably after ten days and at the same time iron in the form of Blaud's pills or with arsenic is begun. As compared with the milk diet, recurrent hemorrhages are less frequent and the gastric pains are alleviated more readily and the general condition improves quickly. A large number of the patients were again seen a year after the treatment; the majority had experienced no further trouble.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, FEBRUARY 27, 1904.

LEPROSY AND FISH-EATING ONCE MORE.

Certain recent newspaper articles have called attention once more to Dr. Jonathan Hutchinson's theory that the consumption of tainted fish by seacoast populations is the principal cause, perhaps even the only cause of the spread of leprosy. Those who have been subscribers of the Medical News for the last seven or eight years will doubtless remember that our correspondent who was present at the International Leprosy Conference, held in Berlin in October, 1897, summed up what was said at that time with regard to any possible etiological connection between fish and leprosy. Dr. Hutchinson did not attend the conference in person, but he sent his paper to be read and while it was not discussed much during the session itself it was very freely criticized afterward.

The present writer was in attendance at that conference and remembers distinctly that not a single authoritative expert in leprosy agreed even in the slightest degree with the views expressed by Dr. Hutchinson. It must not be forgotten that owing to the circumstances under which that conference was held, at the invitation of the German government, practically all of the most distinguished authorities on leprosy in the world were present. They all seemed inclined to laugh at the idea urged by Dr. Hutchinson.

Such an attitude of mind on the part of all the medical authorities on a given subject may not, it is true, of itself prove the baselessness of a theory. Those who know medical history know very well that most of the theories which have afterward proved fruitful of important advances in medicine have been very bitterly opposed by distinguished authorities when first suggested. In fact the rule has come to be well established that if a new idea comes from a young man and is opposed by all the older men present at a meeting, it is very possible that there may be something valuable in it. However, this cannot be considered at all the case with Dr. Hutchinson's theory. It has now been before the public for nearly twenty-five years, yet without the slightest scintilla of actual evidence to support it. Dr. Hansen, who is very well known for his discovery of the bacillus of leprosy and for important clinical studies on the disease in Norway, tried, for several years, just after the discovery of his bacillus, to find some trace of it in tainted or in fresh fish. He did not succeed, however, in finding anything that would justify him in connecting the consumption of fish in any way with leprosy.

In a letter to the London *Times* several months ago, Dr. Hutchinson advanced what he considered a new and convincing substantiation of his theory of the connection between fish-eating and leprosy. He said that since the Reformation leprosy has disappeared from England. The reason for this disappearance is, according to his views, that before the Reformation the English people were bound by the precept of abstinence from flesh meat on many days in the year, altogether nearly one hundred in all, and as a consequence were much more likely to contract the disease because they were compelled to eat fish. When the obligation of this precept of abstinence was no longer binding then fish-eating went out of practice and leprosy disappeared.

There are two defects in this argument. One is that leprosy had already almost completely disappeared from England at the beginning of the sixteenth century, while the English Reformation did not occur until near the middle of that century. The other defect is that leprosy equally disappeared during the fifteenth century from every other country in Europe, as well as England, though most of the countries continued faithfully to observe the precept with regard to abstinence just as in the centuries before.

At a leprosy conference, held in London last year, the whole subject of the etiology of leprosy,

direct and indirect, was thoroughly discussed once more. Dr. Jonathan Hutchinson's fish theory received just as little attention as it did at the International Conference in Berlin six years ago. Sir Patrick Manson, who is considered one of the best English authorities on the diseases of the East, for his practical advances in which he was knighted not long since, scouted the idea of the consumption of fish having anything to do with the spread of leprosy. One Anglo-Indian physician brought with him to the conference the history sheets of over 100 cases of leprosy in patients who, owing to their religious principles, had never eaten fish, but had lived exclusively on rice. A physician from the island of Ceylon reported that leprosy existed only at a few points along the coast, though the inhabitants of the island lived almost universally on fish. When this food material reached the interior, owing to faulty methods of curing, it was not infrequently in a state of such poor preservation that it would exactly suit the requirements of Dr. Hutchinson's theory for the production of leprosy. Leprosy, however, is absolutely unknown in the interior of the island. On the other hand it has been shown that on the island of Madagascar, where, in the interior, many of the inhabitants live exclusively on rice, leprosy is not only not uncommon, but lepers are very frequent and require to be specially cared for by the missionaries.

In spite of every discouragement and the complete disagreement from his opinion of every prominent authority on leprosy, Dr. Jonathan Hutchinson continues to cling to the etiology of leprosy, which he formulated now nearly a quarter of a century ago. His letter to the London *Times*, making a religious matter of it, brought his ideas for the first time prominently before the public. His theory has never been given any prominence in medical literature. We shall, however, presumably have further revivals of it. Let us hope that physicians at least, will not give any credence to this bit of theory, which is absolutely unsupported by observation of any kind, formulated out of the whole cloth of theoretic consideration. Virchow's denunciation of it in 1897, as a medical doctrine likely to hinder the development of medical knowledge of leprosy by occupying observers' minds with investigations that he was sure would bear no fruit (he surely was in a position to judge, since his first article on leprosy was written nearly fifty years before he opened the discussion at Berlin), shows what the true basis of medical opinion with regard to it must be.

CYSTIN.

Through the interesting researches of Mörner and Embden it has been conclusively established that the sulphur of the albuminous molecule is present largely, if not exclusively, in the form of a cystin complex, and can be obtained as such on hydrolysis with boiling mineral acids. The possibility was thus furnished of establishing the chemical constitution of cystin, and a basis created for profitable investigations into the sulphur metabolism of the body. Before this, researches in this direction were rendered extremely difficult through lack of material, as the urine, *i.e.*, concretions obtained from cystinuric individuals, represented the only source of supply. At the present time it is a very simple matter to prepare as much cystin as may be required for an investigation from horn shavings, or, still better, from human hair.

The immediate result of the investigations of Mörner and Embden was the establishment of the structural formula of cystin, by Friedmann. Baumann had previously regarded cystin as a methyl-glyoxylic acid derivative and as related to the mercapturic acids. This view Friedmann has disproven and he has shown conclusively that the cystin derived from albumins is the disulphide of an α-amido-β-thiolactic acid; in other words, it is an α-diamido-β-dithiodilactic acid. The synthetic production of the substance which Erlenmeyer has quite recently accomplished has borne out the correctness of Friedmann's reasoning. This fact established, Friedmann could show that an oxidation cystin can be converted to cysteinic acid; which apparently represents the sulpho-acid of cystein; this in turn yields taurin through loss of carbon dioxide. The long-thought-of connection between cystin and taurin was thus established and the probable antecedent and source of the taurin ascertained.

Long ago Kunkel and Spiro had shown that an increase of the ingested albumin to eight times the usual quantity only led to an increase of double the amount of normal sulphur in the bile. These experiments were made on dogs provided with biliary fistulæ, but led to no definite conclusion. Quite recently v. Bergmann resumed these investigations, but substituted cystin for the increasing amount of sulphur in the food, the diet remaining constant. The results were most interesting. It was ascertained that the administration of cystin did not lead to an increased elimination of sulphur in the bile. If, however, cholalic acid was simultaneously administered the

sulphur output was at once increased. As the sulphur in the bile is only present in the form of taurocholic acid the conclusion is justifiable that cystin is normally transformed to taurin and eliminated as such, providing that a sufficient quantity of cholalic acid is available. Another source of taurin is at present not recognized.

The question that then arose had reference to the fate of the administered cystin, in cases in which cholalic acid was not given simultaneously. To this end Blum administered cystin to dogs in various ways. As a result it could be shown that the administration of cystin by the mouth or subcutaneously did not lead to cystinuria, even when very large amounts were given. Its intravenous injection, on the other hand, led to a certain grade of cystinuria, unless the cystin was introduced into a mesenteric vein, in which case no cystin could be demonstrated in the urine. This fact finds its logical explanation in v. Bergmann's demonstration of the transformation of cystin to taurin. As the ability of the organism to eliminate taurin in the bile is limited by the amount of cholalic acid which is available at the time, we may assume that in the event of an increased production of cystin the normal organism will oxidize a certain amount of the taurin to sulphuric acid. As a matter of fact Blum found no increase of the lead blackening sulphur of the urine, when moderate quantities of cystin had been given.

These experiments throw light upon the interesting metabolic anomaly which is occasionally observed in the human being, and which manifests itself in the appearance of cystin in the urine. Various possibilities suggest themselves as probable explanations. That the anomaly depends upon an unusually intense hydrolysis of the ingested albumins in the gastro-intestinal canal, and a flooding of the circulation with cystin that has been absorbed, can probably be eliminated on the basis of Blum's feeding experiments. For an unusual degree of protein destruction in the tissues with the simultaneous liberation of unusually large amounts of cystin there is likewise no basis. We are consequently forced to the conclusion that the cause of the cystinuria must be sought either in an impeded transformation of the cystin to taurin or in the fact that a sufficient quantity of cholalic acid is not available for its elimination as taurocholic acid. Experiments on cystinuric individuals in this direction will not unlikely yield interesting results and may be anticipated in the near future.

PHILLIPS AND COMPANY.

THAT love is not always the fulfilling of the law seems lately to have been exemplified by Chief O'Neal, at Chicago. For he has raided the "Climax Marriage Club," of 1418 LaSalle Avenue, and ruthlessly arrested A. W. Phillips and six "young lady clerks." These, with the wife of the proprietor, who escaped, seem to have been carrying on a most profitable business in the sale of philters and potions, and as ministers of love, and feeders of its sacred flame. The police had, it appears, been watching the place for some months, but the time seems now to have arrived when the best-laid schemes of "Doc Phillips" have gone a-gley.

Numberless letters from all parts of the country were seized, the signatures of which—many of them from well-known people—only go to show, that fools' names, like their faces, may bring their owners into trouble, even when seen in private places. Love may be blind, but jurors are not, and though these signers of the declaration of independence of thought and action, may get nothing worse, they are likely at least to lend their names to the rude annals of the police court. There are, moreover, some very germinant seeds of scandal, scattered like plums, here and there in the correspondence, which, under the forcing process of blackmail, might produce a very rank crop of ill-smelling weeds. The wife, and presumptive partner of the proprietor, too, has not been captured, while the six little maids have been released. So that the securities of the patrons of the club can hardly be classed as "listed," and most certainly not as "preferred."

The principal source of revenue to the firm seems to have been the dispensing of drugs and nostrums that are unknown, in their present combination, to the United States Pharmacopœia, a large quantity of which were captured on the premises. Of these the "Silver Pill" appears to have been the "leader" in their trade-producing efforts, and for it they claim, in their circular, all the virtues that have been hitherto ascribed to the classic Pink Pills for Pale People and the much-vaunted Mormon Wafer. They were seductively put up, in attractive-looking boxes, and were sold at the remarkably low price of twenty-five cents per box—five for a dollar; probably on the principle of large sales and small profits. For the product of the illicit still of the medical world is apt to be much more expensive to the victim than the professional services of the regular practitioner. They were made fresh every hour, as

they claimed to meet the demand, and also perhaps to correspond to the birth-rate of the purchasers.

Each and every original package contained a printed slip of directions, which were explicit, and as easy to understand as the diagnosis of the ills for which they were to be given. "One pill every half hour after eating meals, and also take one every half hour when with the lady of your heart. They tone the nerves. Without them no one can be successful in courtship or business."

Can anything be more simple? So, if this be true, why should not suffering humanity, on whom the cloud of relaxation has fallen, take refuge in the silver lining of this bolus? Why not a silver pill? In fact, as Grosvenor sang, "Why not a silver churn?" All things come to those who wait, and what could be more charming than sitting with the "lady of your heart," with one hand in durance vile, grasping the pellet, while the fingers of the other twine about the glass of water with which to wash it down? Meanwhile the adored one lingers with the opened watch before her, waiting to call "time," and ready to administer the half hourly pill. Pills that are to "tone" the recalcitrant nerves, and "slowly warm the creeping life-blood to the last." Pills that are to render the laggard in love, and the dastard in war, men of action and affairs! What matters time, if business is increasing and every moment only serves to hasten the maturity of the coupons as the bonds increase and multiply?

It is love that makes the world go round, and if Phillips and Company, in connection with their six little maidens, can manufacture and dispense a sufficient number of silver certificates to increase the number of its revolutions—even at the ratio of two to one—this physic certainly deserves a better fate than to be thrown to the dogs of a confiscating municipality.

Great as the advantages of this rejuvenator are, and vast as the blessings may be, that flow from its constant use, yet this modern philanthropist goes one step farther, and states in a Biblical manner—as if keeping his best wine until the last—"that they are guaranteed to cure *bashfulness* in three months or less."

It is here that we draw the line. We acknowledge that it is not always just to require the testimony of our own special senses to confirm the statements of another. We admit that many inhabitants of the inland States do not believe in the existence of the sea-serpent, simply because they have not themselves seen it; while it is impossible to induce the majority of seafaring men to realize that there is any peculiar knowledge derived from previous experience that would prove useful in the handling of horseflesh. Therefore we do not say that bashfulness does not exist in Chicago, but we do believe, that if a person has arrived at adult age in the Western Metropolis, and has preserved any traces of it, his case has become so chronic, that it is far beyond help from any mere drug or course of treatment. Like the furunculous diathesis of Job, it has come to stay and has become bone of his bone, and flesh of his flesh.

Moreover, bashfulness is an attribute of callow, unfledged adolescence—the bloom of youth that custom withers. So if this Western Mephistopheles can strip the beard and wrinkles off from Faust, we welcome him. But can he raise the dead and show us Margherita as she used to be?

> "It might have been a boyish love,
> Ah weary woman—listless lover,
> Again to feel that fierce wild thrill
> I'd give—but who can live life over?"

ECHOES AND NEWS.

NEW YORK.

West End Medical Society.—The third regular meeting for 1904 will be held at the residence of Dr. Walter Mendelson, 159 West Seventy-fourth Street (telephone, 282 Columbus), on Saturday evening, February 27, at 8:15 o'clock. The paper of the evening will be by Dr. Henry L. Shively. Subject: "A Clinical Study of Myoidema, with Especial Reference to its Occurrence in Pulmonary Tuberculosis."

Surgical Outfit for Fire Companies.—Twenty-five leather cases, containing emergency medicines and surgical instruments, are to be furnished to every company in the Fire Department of New York City. With these cases always available, any one with surgical knowledge present at a fire may treat wounds on the spot. It is possible, too, that instruction in "first aid to the injured" will soon be given to all firemen.

Typhoid at Watertown, N. Y.—A preliminary report on the typhoid fever epidemic at Watertown, where there have been 300 cases of the disease since January 1, has been made to the State Health Department by Prof. O. H. Landreth, consulting engineer of the department, who is making an investigation of the situation. The epidemic, according to advices received by the department, is still raging with unabated vigor, five or six new cases being reported daily. Prof. Landreth, in his report, says that the city's water supply is apparently the most probable cause. The source of supply is the Black River. There are numerous villages located on the stream above Watertown. Above the city and on the watershed of the river a number of typhoid cases have been located, and Prof. Landreth believes that an accumulation of polluting matter on the watershed was washed down into the river during a thaw in the latter part of December. Watertown is constructing a rapid sand filtration plant, but it will be several months before any relief from this plant can come,

and meantime the people have been urged to boil thoroughly all of the water used for drinking purposes.

Seaside Hospital for Tuberculous Children.—Tuberculosis is to be attacked in a new quarter by the New York Association for Improving the Condition of the Poor, 105 East Twenty-second street, which has appropriated $15,000 for the maintenance at the seaside of children less than fifteen years old, who suffer from non-pulmonary forms of the disease. This will be the first seaside hospital exclusively for tuberculous children in America, although in France such cases are, as a rule, treated at the seaside, it being generally held by experts that the ocean air is the best for such patients whose lungs are unaffected. There are said to be nearly 4,000 children in the New York tenements suffering from scrofula, tuberculous joints, and lymph lobes. Several hospital beds have been provided for them, and the New York Orthopedic Hospital and the Society for the Ruptured and Crippled give special treatment, but the new hospital appears to be a much needed institution in the same field.

Volunteer Surgeons for Japan.—Surgeons and nurses are appearing at the Japanese Consulate every day to volunteer their services, and while they are not needed now, Consul General Uchida takes their names and addresses, which he forwards to the Japanese Minister at Washington. Dr. Anita Newcomb McGee asked Mr. Uchida to be allowed to go to Japan with a corps of trained nurses and attendants for the Japanese hospital service, either in the field or wherever they could be used to advantage. The Consul General, after consulting with the Japanese Minister, accepted the offer, and the volunteers will be sent as soon as they are ready. The war fund of $5,000,000 which is being raised by the Japanese residents of this country is constantly growing, and already almost $100,000 has been subscribed, with promises of more than twice as much more. Consul General Uchida has received two checks, one for $10,000 and the other for $5,000, both of which were sent by Japanese merchants of this city. Besides contributions of money, offers are daily made to the Consul of equipment for the Japanese Red Cross Society. One American firm has sent to the Consul General asking him to accept five large field ambulances, to be shipped at the donor's expense. Various firms of manufacturers of supplies and drugs have offered large quantities of their goods.

Opening of the New Mount Sinai Hospital.—Preparatory to the removal of the hospital to its new buildings at Fifth avenue and One Hundredth street, the admission of patients has been discontinued at the old hospital. A reception will be held at the new buildings on the afternoon and evening of March 15 and 16. Patients will be admitted to all departments Monday, March 21.

Annual Reunion and Dinner.—The seventh annual reunion and dinner of the Associated Alumni of Mount Sinai Hospital was held at the Freundschaft Society Building, Park avenue and Seventy-second street on Wednesday, February 17. Dr. G. L. Brodhead presided. The officers elected for the ensuing year are as follows: Dr. Edwin Sternberger, President; Dr. Charles Goodman, Vice-President; Dr. Leo B. Meyer, Secretary, and Dr. Eugene H. Eising, Treasurer.

Exoneration of Bellevue.—At a Coroner's inquiry into the death of Adolph Drucker, whose friends claimed that he had been beaten and drugged in Bellevue Hospital, the attendants were relieved from all blame. Coroner Jackson, in charging the jury, said that he thought that Drucker had died of alcoholic meningitis. "I examined the body," said the Coroner, "and found no marks of violence. Two patients in the hospital after Drucker's death said that he had been awfully maltreated, and that his death was due to this treatment. The men were afterward arrested on I-know-not-what charge, and what they say, therefore, must be taken with a grain of salt. I looked into the charges against the hospital, and found that Drucker had been treated as well and kindly as any other patient. Of course, he may have died of drugs—his life was heavily insured—but that could only be ascertained by an autopsy, and his body was removed to Westchester county before this could be performed. It can only be exhumed by a request of the District Attorney to the Supreme Court. Or Drucker may have had a fall and fractured his skull." The jurors, without leaving their seats, decided that Drucker came to his death through causes unknown, and exonerated the hospital from all blame.

The Medical Society of the County of New York.—At the annual meeting of the Medical Society of the State of New York, held in Albany on January 26, 1904, the following resolutions were unanimously adopted:

Resolved, That the Report of the Joint Committee of Conference be accepted and that the proposed Agreement for the Consolidation of the Medical Society of the State of New York and The New York State Medical Association be and the same is hereby approved, and the President of the Society is hereby authorized and directed to execute the same in the name and behalf of the Society, and the Secretary is hereby authorized and directed to affix the corporate seal thereto; and be it further

Resolved, That the Committee of the Society heretofore appointed for the purpose of bringing about the consolidation, namely, Dr. Henry L. Elsner, Dr. A. Jacobi, Dr. A. Vander Veer, Dr. George Ryerson Fowler and Dr. Frank Van Fleet, be and they are hereby continued as such Committee, with full power and authority to do whatever may be necessary to carry the Agreement into effect.

Action on the adoption of the enclosed report, together with the proposal of resolutions ratifying the action of the State Society, will be taken at the stated meeting of this Society, to be held Monday, Feburary 29th, 1904, at 8:15 P.M. Ratification of the action of the State Society by each County Society is requisite for the completion of the consolidation.

The Manhattan Dermatological Society.—Regular monthly meeting held Friday evening, Feb. 5, 1904, at the residence of Dr. E. L. Cocks, with Dr. I. P. Oberndorfer presiding.

Dr. B. F. Ochs showed a case of congenital venous angioma, occupying the right side of face and forehead; the child is now fourteen months old. At birth the nevus was a deep blue, but the mother states that the color is fading gradually, so that at present it is of a pale sky-blue color, the latter best observed in daylight. The upper half of nevus is covered with fine hairs. Dr. Ochs also showed his case of chronic onychia (presented at the January meeting). Microscopical examinations of scrapings and nail sections failed to show the favus, or tricophyton mycelia or spores. Dr. Gottheil termed the condition onycholysis, probably of non-parasitic origin. Dr. Whitehouse said present appearances did not suggest favus or ringworm. Psoriasis he could likewise exclude, owing to the degree of nail preservation after nine years' duration. He would look for some other origin not necessarily parasitic.

Dr. J. Sobel presented a case of acne indurata, showing result of treatment; of two years' duration and involving the face, chest and back. The usual hygienic and dietetic regulations advocated, cod-liver oil and pill. calcium sulphid internally; and locally lotio alba, unguentum of salicylic acid, sulphur and resorcin and the curette. Large acne nodules were treated with injections of hydrogen peroxid; the latter had a marked effect in reducing the large indurated papules. Dr. Cocks likewise used the curette and saw good results following the use of hydrogen peroxid. Dr. Gottheil would not be too enthusiastic concerning the value of calc. sulphid given internally. He also uses the curette and saw no scarring following. Dr. Bleiman stated treatment should be directed toward keeping down the hypersecretion of fat, which was the chief factor in producing sebaceous plugs and acne papules. Locally, sulphur, resorcin and naphthol ointments and the use of the curette.

Dr. E. L. Cocks presented two cases: (*a*) Case of hypospadias in a boy of ten years; the question of immediate or remote operation was discussed. (*b*) Case of squamous palmar syphilide. A young man, a fireman, twenty-eight years old, gave history of infection some years ago; the secondary symptoms and signs cleared up in due time, but a lesion of both palms is obstinately persistent and extremely rebellious to treatment. Both palms show induration sharply defined, smooth and glistening; no fissures. Dr. Gottheil suggested the injection method in these cases, claiming better and more rapid results. Dr. Sobel stated, the absence of fissures, the presence of marked induration and the sharply defined margins favored the diagnosis of syphilis. Dr. Whitehouse said these cases are always difficult to treat and prove rebellious to any form of treatment; he suggested local treatment was of prime importance. Dr. Oberndorfer also said he would pay more attention to local methods; internally antispecific treatment heroically administered.

Dr. W. S. Gottheil presented the following cases: (*a*) Acne cornea (shown at January meeting). New lesions were observed on the face and three or four more new ones developed on the hands. (*b*) Bromoderma; a papulopustular eruption on abdomen and thighs and smaller papules on the face following the administration of bromides. (*c*) Dermatitis herpetiformis; a young girl of fourteen years gave a history of repeated attacks of papulovesicular lesions on the face and body; the present attack is confined to the abdomen, groin and thigh, and consists of papules, vesicles and pustules, singly and in groups. The patient is never absolutely free from one of these outbreaks. Drs. Ochs, Sobel and Cocks agree in the diagnosis; history of recurrence was strongly suggestive of the condition. Dr. Whitehouse likewise favored this diagnosis, owing to the history, multiformity of lesions and the intense burning and itching. Dr. Abrahams would call it vesiculopustular eczema. Dr. Oberndorfer observed pediculi on the head; he thought the body lesions may have had some such connection and if so, he looked upon it as an irritative pustular eczema. Dr. Gottheil stated that an impetigo or a pustular eczema may resemble a dermatitis herpetiformis, but there was no such history of recurrence. (*d*) A woman, showing large crescentic patches, distinctly erythematous, well-defined margins, the latter slightly scaly and the centers pale; the clearing centers showing slight pigmentation. Lesions of several months' duration. Drs. Abrahams and Oberndorfer think it may be a syphilide. Dr. Sobel termed it mycotic eczema. Drs. Cocks and Bleiman recognized a resemblance to eczema marginatum.

Dr. Holding presents for Dr. Pisko the following cases, showing results obtained under X-ray treatment: (*a*) Epithelioma on lobe of right ear; was given three five-minute exposures every fifth day, then twice a week for ten minutes; a slight dermatitis developed, and treatment was temporarily suspended. (*b*) Congenital nevus pilarus pigmentosus on forehead; given eighteen treatments; the only result so far observed was falling out of the hair. (*c*) Acne rosacea; was under treatment for two years with ointments and other local applications; since October 12, 1903, has had thirteen X-ray exposures and some improvement is noticed. The therapeutic value of the X-ray in dermatology was discussed.

Hours for Bakers.—A decision was handed down in January by the New York Court of Appeals sustaining the law prohibiting the employment of bakers for more than sixty hours per week or more than ten hours per day, says *Charities*. Especial significance attaches to the ground taken, the statute being sustained not as a labor measure but as an exercise of police power for the protection of public health. The law had been attacked as unconstitutional in its interference with the right of contract. Three judges apparently held to the latter view and the position of the majority was reflected in an opinion written by Judge Parker. To quote in brief: "That the public are generally interested in having the bakeries and confectioners' establishments cleanly and wholesome in this day of appreciation of and apprehension on account of microbes, which cause disease and death, is beyond question. It can be safely said that the families of to-day are more dependent upon the bakers for the necessaries of life than any other service of supply. That being so, it is within the police power of the legislature to so regulate the conduct of that business as to best promote and protect the health of the people. Is it possible that any one can question that the sole purpose of the legislature is the safeguarding of the public health when it provides for floor, ceiling, and sidewalls, such material as that they may be readily cleansed; compels the keeping of flour and meal-food products in dry and airy rooms, so arranges that the storing facilities can be readily cleaned and prohibits the keeping of domestic animals within such rooms? It is reasonable to assume from the statute as a whole that the legislature had in mind that the health and the cleanliness of health workers were of the utmost importance; that a man is more likely to be careful and cleanly when well and not over-worked than when exhausted by fatigue, which makes for uncleanliness and slovenly habits and tends to dirt and disease. If there is opportunity—and who can doubt it?—for this view, then the legislature had the power to enact as it did and the courts are bound to sustain its action as justified by the police power. I hear but one argument advanced for the purpose of convincing the mind that the object of this statute is not to protect the interest of the public, and that argument is that it is to be found in the labor law. Therefore, it is said, it is a labor law and not a health law. The question presented by this argument is: Does the label or the body of the statute prevail? Does calling a statute names deprive it of its intended and real character? If a statute relating to banking happens, in the course of qualification, to be incorporated as an article in the general corporation law, does it cease to operate upon the banking interest? I submit without argument that the ques-

tions answer themselves. Medical authorities without number classify workers and bakers in confectioners' establishments with porters, stone cutters, and file grinders and other workers whose occupation necessitates the inhalation of dust particles and hence predisposes its members to consumption. Medical opinion and statistics bearing upon that subject, standing alone, fully justify the section under review as one to protect the health of employees in such establishments, and it is the duty of this court to assume that the section was framed not only in the light of but with a full appreciation of the force of the medical authority bearing upon this subject—authority which reasonably challenges the attention of the philanthropist."

PHILADELPHIA.

Increase in Pneumonia and Typhoid.—Of the 605 deaths reported for the week ending February 20, 125 were due to pneumonia. Officials of the Bureau of Health, who regard the disease as contagious, are considering the advisability of issuing a circular calling attention to precautions against the disease. During the week there were 142 new cases of typhoid fever, the largest number for one week since April, 1903.

Vaccine Corps Paid.—The thirty-six physicians comprising the vaccine corps of the Bureau of Health, who were succeeded by the recently appointed Medical Inspectors, received their pay on Monday. The pay aggregated $39,847. Between July 10 and December 31, 1903, they vaccinated 207,000 persons. Reports indicate that 75 per cent. of the vaccinations were successful.

To Regulate Meat Inspection.—Governor Pennypacker has recently appointed a commission to formulate rules for the suppression of tuberculous cattle in the State and also provide for a uniform system of meat inspection. This will be made possible by deciding upon a determining point when meat may be dangerous for use and hence its sale prohibited. At present no uniformity exists, although the meat inspection service in this city has lately been much improved. The report of the commission will be made to the State Live Stock Sanitary Board, which will promulgate the rules among the meat inspectors throughout the State. The Secretary of the Board states that about 3 per cent. of the cows from herds about Philadelphia are tuberculous.

Address by Dr. Northrup.—Dr. W. P. Northrup, of New York City, was the guest of honor at the annual dinner of the J. C. Wilson Medical Society of the Jefferson Medical College, February 19. Previous to the dinner Dr. Northrup addressed the students of the college, his subject being "Joseph O'Dwyer, M.D.; his Methods of Work on Intubation; The Measure of his Success; The Interest of both to Young Graduates."

Additions for Methodist Hospital.—Additions costing $300,000 are projected for the Methodist Episcopal Hospital during the present year. Among the new buildings will be a dispensary, nurses' home, power house, and kitchen. A new ward for charity patients is also contemplated.

Sites for Health Camps.—In a recent address before the American Philosophical Society on the prospects of forestry in Pennsylvania, Commissioner J. T. Rothrock emphasized the need for establishing sanatoria and camps for the treatment of consumptives. That Pennsylvania is equipped for this purpose was proven by the statement that the State owns some 600,000 acres of land better adapted to forestry than agriculture, having been purchased at prices varying from 7 cents to $3.85 an acre. This land is distributed through twenty counties and offers many excellent sites for camps.

New Medical Magazine.—The first number of *The Therapeutic Review*, a monthly magazine, to be issued under the editorial management of Dr. Horatio C. Wood, Jr., has made its appearance. It is a well-printed journal of 40 pages and is to be published at $1.00 per year. The purpose of the new publication can best be given in the following extract from the editorial announcement: "Our purpose is to offer a journal which will not only be given up exclusively to therapeutics, but which shall give as complete a summary as possible of all that is being done, throughout the world, in the treatment of disease. We intend to present every month a copious résumé of the important therapeutical literature of the world in a concise but readable form."

Vital Statistics Modernized.—The International Classification of deaths is now being used in filing the vital statistics of Philadelphia. This system was put in force on January 1, thus making it possible to compare the statistics of this city with those of other large cities of the world. It is stated that the statistics of the past four years will be practically useless for the next census, owing to the failure to adopt during that time the classification mentioned.

CHICAGO.

Presentation of Loving Cup to Dr. Quine.—The Senior Class of the Medical Department of the University of Illinois (College of Physicians and Surgeons), at its annual reception given Feb. 9, in honor of Dr. Wm. E. Quine, the Dean, presented him with a silver loving cup, as this marked his fifty-seventh birthday anniversary, his thirty-fourth anniversary as a medical teacher, and his twenty-first anniversary as a member of the Faculty of the College.

Suicide by Carbolic Acid.—The use of carbolic acid is not a passing fad among suicides. It is an established custom, due primarily to the fact that the legitimate uses of the acid are so numerous that it is easy for almost any person to give a druggist a plausible reason for the purchase. Death by carbolic acid is death by torture, but the would-be suicide who is in real earnest does not stop to bother himself about a few moments or a few hours of agony. The Retail Druggists' Association favors the passage of a City Ordinance regulating the sale of this poison, and the Council will do well to give the proposal careful consideration. It is said that the placing of restrictions upon the free sale of concentrated solutions will do much good, with little inconvenience to the public, inasmuch as the more diluted solutions are perfectly satisfactory for most legitimate uses. The concentrated solutions are fatal, but the weaker solutions are much less dangerous. There is reason to believe that a properly framed ordinance would reduce the number of suicides.

Mortality of Diphtheria.—Between Oct. 5, 1895, the date of the first case treated, and Dec. 31, 1903, the antitoxin administrators of the City Health Department have treated 7,435 cases of bacterially verified diphtheria, of which number 479 died, a mortality rate of 6.44 per cent. The average mortality without antitoxin still remains at about 35 per cent.

Influenza.—The weekly Bulletin of Health has this to say with reference to influenza: "When a person is ill with influenza, it is better not to visit him or, if a visit is imperative, it is advisable to avoid unnecessary personal contact. After the interview, the hands should be thoroughly washed in an antiseptic solution and the

outer garments should be aired by being exposed to a current of fresh air, or, better still, to the direct rays of the sun. The condition of the general health should be maintained by plenty of outdoor exercise, by good food, and the avoidance of indulgence in alcohol. At the onset of the initial symptoms, the patient should remain in bed and should at once obtain medical advice. No reliance should be placed on popular remedies, for the complications are so grave that the best possible treatment is required. Do not fool with the grip, but go to bed and send for your doctor."

Cryoscopy.—Dr. Theodore Ticken read a paper on this very interesting subject before a recent meeting of the Chicago Medical Society, in which he reviewed in detail the evolution of cryoscopy and the literature up to the present time. He sums up the conclusions of other workers along similar lines and compares the results with those he obtained. During the past eighteen months he has examined the blood and urine in 330 cases, making in all over 500 estimations of the freezing points. He finds that the results obtained by Koranyi, Kümmel, Caspar and Richter, Rumpel, Tinker, and others, are correct, and that the slight differences may be accounted for by errors in technique. He used the Beckman apparatus for both the blood and urine, and gives the normal freezing point of blood at 0.56° C. below zero, as found by previous workers. The urine, as collected for the usual twenty-four-hour specimen, freezes at 1.46° C. in the average normal individual, but the normal limits vary from .98 to 2.56°. He finds that the freezing point of the mixed urine does not give us much information as to the functional activity of the kidneys, and that a catheterized specimen from each kidney is necessary to be of help to us. The freezing point of the blood is nearly constant (0.56°), and the normal variations are much less than in the urine—.55 to .57° C. being usually given, but we must not be misled by the variations occurring in the freezing point of this fluid, as it, too, is subject to outside influences. He thinks that cryoscopy will be of value to us in many cases, especially when used in connection with the other methods of diagnosis, as ureteral catheterization, the phloridzin test, and careful chemical and microscopical examination.

Physicians' Club of Chicago.—At a meeting, held Feb. 16, Graft was the subject for discussion. Mr. Clarence Darrow, the eminent lawyer, defined graft as "the effort of any human being to take from society or from another human being or animal more than he really gives to society in return." Great grafts are done inside the law. The wise grafter never undertakes to get something contrary to the law. He undertakes to fix the law so that he can get something according to the law. It is more profitable and safer. The cheap grafter, who does not understand his business, and does things by retail instead of wholesale, who has little voice in making or administering laws, undertakes to graft contrary to the law. Great capitalists graft inside the law. It is easier for them to choose their agents and their tools to fix the law the way they want it, and they get what they want without running the slightest possible risk. The grafter is a product of his environment. There is considerable grafting in the legal profession. Indirectly, that is what the legal profession is for, said Mr. Darrow. It is a business chosen by certain men because they think by pursuing it they can get more than they can by pursuing any other business they are familiar with. He said it speaks well for the medical profession that there are few doctors in Congress or in legislatures. Dr. Harold N. Moyer discussed medical graft. He said he has made inquiries from a large number of members of the profession, and has been unable to find anybody who knew anybody who grafted, or knew anything about graft in the medical profession. He has found one or two men who said they knew of somebody else in the profession grafting, but upon running the inquiry down, he found it was false, and he received the word of the man himself to authenticate it. Dr. J. Clarence Webster asked about the Chicago surgeons in high places, who contrive with country practitioners to send them patients. Such men existed, and one could put his fingers on them. It is not necessity that stimulates these men to carry out this nefarious practise, which is not only detrimental to their self-respect, but a temptation to weak brothers with whom they come in contact. Within the last month he saw a circular signed by a surgeon who is connected with one of the well-known hospitals of Chicago. This circular was sent around to various physicians in Illinois and neighboring States, offering bribes for patients sent to him. He knows of the same thing having been done by a professor in one of the best medical schools in a neighboring State. These men are not starving. They do not require to do that business, but they do it. What is the explanation? Not necessity, but deviltry—degeneration, and as long as men in high places do this, he said it is absolutely folly to expect the struggling practitioners, who are in the position of being bribed, not to be bribed. Dr. Palmer Findley said the burden of medical graft falls upon the young physician and surgeon. He does not think any surgeon has to graft for bread and butter. Going out into a neighboring town two or three months ago to operate on a poor farmer's wife for a small fee, a physician, after the operation, showed him a card from an agent of a surgeon in Chicago, offering fifty per cent. commissions. This practitioner also showed him a letter from a local surgeon who solicited cases for twenty-five per cent. commission. Another case was mentioned of a physician in the same town who had gone personally to the attending physician in a case in behalf of a Chicago surgeon, and he had openly declared time and again that he was receiving a division of fees. The remedy should be the one President Roosevelt suggested for trusts—publicity—publicity through organizations, so that it will be impossible for men who are professors in leading medical schools and officers in medical societies to divide fees or give commissions. Mr. Wm. H. McSurely defined a grafter as one who allies or attaches himself to some outside interest, some interest apart from the main motive of his life, for the purpose of getting from that outside interest something that will be beneficial to the main motive of his life. He then spoke of lawyers and doctors as church grafters, the society grafters, etc. Dr. G. Frank Lydston spoke of the physician in politics and public affairs, saying that the doctor who devotes a portion of the years of his life to politics and to the public service is forever damned in the eyes of both the public and the medical profession. The reverse is true of the lawyer. In politics the lawyer attracts attention to himself. He said there were very few lawyers who rendered services in the interest of the public without salary, although this was frequently done by physicians.

CANADA.

The Prohibition of Alcohol in Medicine.—An effort is to be made by the Ontario Council of the Royal Templars to direct legislation to prohibit the sale of such patent medicines as contain alcohol in excess of

the quantity sufficient or absolutely necessary to preserve them. At a recent meeting of that body in Toronto, the question was again discussed in all its details and an analysis was produced of several of the well-known patent medicines which rather opened the eyes of several of the good thinking and acting people of this organization. It was abundantly proven that there was from 14 to 40 per cent. of alcohol in many of these preparations, and it was nothing more than whisky habit which caused many people to patronize these so-called cure-alls—another way of taking "morning bitters." For years the medical press has been calling attention to the fact that the virtues, if they were such, were all due to the stimulating qualities they possessed and that these were in all instances due to the alcohol in them. It is gratifying, then, that persistent and consistent agitation has brought the temperance people into line, and that they are uniting as a body in controlling the evil.

Sanitary Barber-shops for Ontario.—One of the members of the Ontario Legislature has a bill before that body seeking to amend the Medical Act, which amendment relates wholly to barber-shops. The legislation will seek to regulate and prohibit the admission to barber-shops of any person suffering from a communicable disease, will provide for the regular and efficient cleansing of the shops and instruments used, as well as the conduct of the barbers as regards personal cleanliness, and looking after the sanitary conditions of the premises. It will also seek to prohibit the employment of any one as a barber while he is suffering from any infectious, contagious or communicable disease.

A Royal Commission for the Prevention of Tuberculosis.—The Executive Committee of the Montreal League for the Prevention of Tuberculosis has appointed a Special Committee to interview the Dominion Government with the object of establishing a Royal Commission for the purpose of fighting tuberculosis. This Committee will draw up a concise scheme of the needs of the Montreal League and will approach the Provincial Legislature to ask for financial aid for the erection of a sanatorium near Montreal. At the meeting Professor Adami and Dr. A. J. Richer, who were present at the Baltimore Tuberculosis Exposition, gave an interesting account of the exhibits and demonstrations. Since June 30, 1903, the Montreal League has had 136 cases under supervision. Of this number 52 had died, six had been transported to their native land, ten were sufficiently improved to be discharged, 14 had been sent into the country, while 63 remained on the active list of the Committee. The medical inspector of the League had made 706 visits, and over 2,000 cuspidors had been contributed.

Annual Meeting of the Montreal General Hospital.—The eighty-second annual meeting of the Corporation and Board of Governors of the Montreal General Hospital was held in that city last week. According to the report the excess of expenditure in 1903 over ordinary income is $13,453 against $10,774 for the previous year. The ordinary income in 1903 was $91,763 against $87,439 in 1902. On December 31, 1903, the endowment fund amounted to $43,500, to which was added during the year $7,000. The hospital is making an endeavor to raise an endowment fund of $500,000. The total number of patients which passed through the wards in 1903 was 3,066 as against 2,878 in 1902, an increase of 188. The outdoor patients numbered in 1903 35,984 against 31,993 in 1902, an increase of 3,991. During the past year twelve nurses received their diplomas.

Marine Hospital Improvement.—The Federal Government will improve the Marine Hospital at Victoria, B. C., to the extent of $3,000.

Personals.—Lord Strathcona has contributed $20,000 to the development of the Science Department of Manitoba University at Winnipeg.

Dr. Claude W. Freeman has been appointed Medical Superintendent of the Hamilton, Ont., City Hospital.

GENERAL.

First Woman M.D.—The first woman receiving the degree of doctor of medicine in Germany was the wife of a pastor named Erxleben. She got it at the University of Halle, just 150 years ago.

Physicians' Pilgrimage to Rome.—The Society of St. Luke and Sts. Cosmos and Damien have made arrangements to visit Rome in a body shortly after Easter of the present year. These societies are composed of physicians, their patron saints having been physicians. It is understood by special arrangements with the Cardinal Secretary of State, Cardinal Merry del Val, that Pope Pius X. will receive the physicians in a special audience. They will also have the special privilege of admission to the gardens of the Vatican. The families of physicians also have the privilege of taking part in the pilgrimage. Specially cheap rates are offered on the railroads and at the hotels; for first-class transportation about $70; for second-class transportation, $58, and for third-class transportation, $48 will be the price of a return ticket from Paris to Rome. This price will also include, besides transportation, all expenses on the way, the hotel bill for six days in Rome, the expenses of carriages in Rome itself, as well as interpreters and guides, and the meals to be taken during the visits in the city. Applications to become members of the visiting party must reach the secretary, Boissarie H. Dauchez, Feron-Vrau, Rue Bayard 5, Paris, France.

Increase of Medical Corps.—Secretary Taft adopted on Feb. 18 a compromise measure providing for the increase of the medical corps of the army. Surgeon-General O'Reilly asked that the corps be increased to 20 Colonels, 20 Lieutenant-Colonels, 110 Majors and 300 Captains and Lieutenants. The General Staff reduced this in their recommendation to 12 Colonels, 18 Lieutenant-Colonels, 120 Majors and 300 Captains and Lieutenants. In reaching a conclusion Secretary Taft remarks that the argument advanced by the Surgeon-General for the larger increase was stronger than the argument against it by the General Staff. He therefore decides to recommend to Congress an increase to 16 Colonels, 24 Lieutenant-Colonels, 110 Majors and 300 Captains and Lieutenants.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, February 6.

THE PHYSIQUE OF SCHOOL CHILDREN IN SCOTLAND—THE WAR OFFICE AND THE MEDICAL SERVICE OF THE ARMY—DRUNKENNESS IN WOMEN—A FRUITFUL MARRIAGE.

DR. ALEXANDER OGSTON, Surgeon in Ordinary to the King in Scotland and Regius Professor of Surgery in the University of Aberdeen, is a man of independent mind, who is by no means disposed to believe, with Pangloss, that all is for the best in the best of all possible world. He incurred great unpopularity among the medical officers of the British Army a few years ago by his plain speech about their shortcomings. He went to South Africa as a volunteer consulting surgeon, and the evidence which he gave before the Royal Commission on the War, based on his personal observations, was by no means pleasant reading to patriotic British-

ers, who would like to think that every department of their military service is thoroughly efficient. More recently Professor Ogston has served on a Royal Commission on Physical Training in the Schools of Scotland. The other day he took the opportunity offered by a meeting of teachers at Aberdeen to deliver his soul on the physical conditions of school children in Scotland, and on the subject of education generally in its relation to health. Like Herbert Spencer he holds that the first object of the educator must be to make the future citizen a healthy animal. In the environment in which the children of the poor live and move and have their being in our large cities this can scarcely be done; bodily defects and deformities of one kind or another are so common that mental education is, in a large proportion of school children, physically impossible. Among those not actually defective, there are many in whom disease exists in a latent form, and almost all suffer from malnutrition to a degree approaching starvation. Nearly all the witnesses examined by the Commission testified that signs of racial degeneracy could everywhere be seen among the rising generation, but a sufficient body of definite facts in proof of this impression was not forthcoming. The Commissioners therefore obtained the sanction of the Treasury to an inspection of schools which might be taken as types by medical experts. Dr. Matthew Hay, Professor of Forensic Medicine and Public Health in the University of Aberdeen, and Dr. Leith Mackenzie, Medical Inspector of the Local Government Board for Scotland, were chosen to make the inspection. The result of their investigations was to show that there was an amount of ill-health, vastly greater than had been anticipated, among young persons attending school. The following passage from their report will give an idea of the state of things: "If the ratios observed by the examiners be admitted, and it may be gathered from their reports that they did not overstate the case, there are in the Edinburgh Board schools 700 cases of unrecognized phthisis, and 458 in Aberdeen, and 1,300 cases of unrecognized heart disease of a dangerous nature in Edinburgh, and 250 in Aberdeen. Of lesser ailments there are in the Edinburgh schools 15,000 children affected with disease of the throat and 7,500 in Aberdeen, and 12,000 cases of ear disease in Edinburgh, and 2,250 in Aberdeen. Of ailing children in the Edinburgh schools there is, even if only half the number of those reported be computed, a total of 10,500, and in Aberdeen 5,708, all of whom are in need of medical attention. Perhaps the most striking evidence that was laid before us of the absolute necessity of a better medical supervision of school children is the statement contained in the Edinburgh report, that out of the total of 299 male children examined in Edinburgh, 259 showed some defect, however remediable, of the ears and throat, and that out of 298 female children examined, 294 showed the same condition of disease." The reports of Drs. Hay and Mackenzie contain other details revealing a condition of matters described by Professor Ogston as "absolutely dreadful." They are, however, beyond denial, and are corroborated wherever similar investigations have been made. For example, quite recently Mr. Cheatle, a well-known London aurist, in examining the ears of 1,000 English school children between the ages of three and sixteen years, found only 432 of them normal; the remaining 568 had disease of the ears. Professor Ogston laid great stress on the mental overpressure to which many children are subjected by the educational methods of the present day. Not only school children, but university students are driven so hard that they either break down under the strain or take longer than the appointed time to complete their studies. At the root of the school difficulty lies malnutrition. It is not by any means only among the poorer classes that this exists. In nearly all schools, and particularly in girls' schools, the food is insufficient in quantity and improper in quality. In connection with this matter Professor Ogston had a good deal to say about "sugar gluttony," which he described as a growing evil in towns. "It may constantly be observed," he said, "that a free indulgence in the mastication of sweetstuff is immediately followed by toothache, due to the production of a ring of disease round the necks of healthy teeth, which are corroded as if by an acid, and the habit leads to the aggravation of already existing caries of the teeth." In some children the sugar habit becomes an infatuation resembling the craving for drink. The Professor ventured on a prophecy that future observers will place sugar gluttony on a level with alcohol as a cause of deterioration in individuals and races. He insisted on the necessity of a thorough medical examination of all children on their first entrance upon school life, all through which they should be kept under skilled observation. Properly trained female inspectors would be an invaluable help. With regard to physical training, Professor Ogston said military drill, though it produces marvelous results in knocking an amorphous recruit into a shapely soldier, is physiologically unfitted for the tender bodies and minds of little children and girls. The Swedish (Ling) system of exercises, practised day after day with no intellectual apprehension of its mechanism, becomes inexpressibly wearisome to children. Moreover, it demands a standard of knowledge in the teacher which it seems nearly hopeless to expect. Even Sweden is beginning to find that its system, though perfect in theory, requires to be considerably modified before it can be used beneficially in schools. Whatever system is eventually introduced as a standard in schools, it cannot, in the Professor's opinion, be anything more than a tentative scheme, to be further perfected in the light of accumulating experience. The recreative element must never be lost sight of; hence no system of training can advantageously replace organized school games.

The War Office, which has become a synonym for red tape, obstructiveness and general inefficiency, is to be reconstituted, root and branch. Among the drastic reforms recommended there is one directly affecting the Medical Service. It is not long since a great victory was won for the medical officers of the army by the position of greater dignity and authority given to their chief. The Director-General was made a member of the Army Board, and as such was on an equality with other heads of departments. The matter was more than one of mere rank; the greater official position made it impossible for the military authorities to disregard the recommendations and demands of the Director-General. Under the new dispensation the Army is to be ruled by a Council, with the composition of which I need not trouble your readers; it is enough to say that there appears to be no place in it for a representative of the Medical Service. The attention of Lord Esher, the chairman of the Reconstitution Committee, has been called to this omission, and he has replied, in the true Delphic style of officialdom, that the position of the medical service is receiving the serious attention of himself and his colleagues. The question is indeed one of sufficient importance to call for their most serious attention, for the experience of the South African, as of every other, war, has conclusively proved that disease kills more men than either bullets or steel, and that epidemics lead to disaster just as surely as defeats. Hence, efficiency in the prevention of disease is an element of vital importance in a campaign. Lord Wolseley owes such laurels as he has won in the field as much to the

skill of his doctors as to his own generalship. Yet, so far from realizing his indebtedness he goes out of his way in his *Soldiers' Pocket Book* to make the remark, which comes with peculiarly bad grace from him, that "medical advice is a good thing—when it is asked for." This spirit of fatuous militarism is responsible for a vast amount of sickness and death from disease in our recent wars. We are, therefore, waiting not without anxiety to see whether the evil tradition of fossilized pedantry which has wrought such mischief in the past is to be kept up under the new *régime*.

In a report presented to the London County Council not long ago it was stated that of 90 arrests for habitual drunkenness, in 89 the offenders were women. A very general impression prevails that the reformation of a female inebriate is practically hopeless. Dr. Branthwaite, the Government Inspector of Inebriate Homes, in his official report of last year, expressed the firm conviction that in the case of women who give themselves a fair chance there is at least an equally good prospect of success as in men. This view is, I think, opposed to that usually held by the medical practitioners who have most to do with female inebriates. Possibly, however, the views may be capable of reconciliation. It may be admitted that women who "give themselves a chance" may be reformed. But how many who are held fast in the bondage of drink do give either themselves or the physician a chance? A representative of the *St. James's Gazette*, one of the most respectable of our evening papers, has lately interviewed six specialists on inebriety with regard to this point. To the question, Can women drunkards be cured? they all replied in the negative. This is doubtless a hard saying, but it represents the opinion of men who have had exceptional opportunities of getting face to face with facts. A well-known physician is quoted as speaking to the following effect: "It is a humiliating confession in the face of so many homes, and systems, and the work the London County Council is doing, but there is no other conclusion. For two years—to give some examples—three of my patients were under treatment in various homes, and subsequently at their own homes. Not one of them is cured. One lost the craving for spirits, but in its place came a craving for drugs, and she is now a complete wreck. The other two drink as much as ever, and have not been at all affected by the system. I have never yet met a complete 'cure.'" The medical officer of a municipal Home for Inebriate Women expressed himself as keenly disappointed with the results of four years' work, and reluctantly admitted that he knew of no single case of complete cure. During that period 215 patients had passed through the home, and of this number 97 had been discharged as incurable, 103 had been sent away partially cured, there had been four deaths, and only eleven were reported "cured." As a matter of fact not one of those eleven women lost the craving, and they are all to-day heavy drinkers. This is attributed to the weak spot in the system, which is the impossibility of keeping patients under thorough supervision after they have left the home. A prominent temperance reformer whose experience of these homes extends over many years, was equally emphatic in his negative reply. "There is no cure," said he, "apart from a resort to strong drugs, which is a greater evil. I have the reports here of a score of homes, at which I am a regular visitor, but in no single instance have I noticed a thorough cure effected. The home is a splendid restraint, but soon after leaving it, a patient gives way again to drink. The perfect remedy is yet to be discovered." This testimony must sadden the heart of every lover of his kind and of every one interested in human progress, for women being, in so large a measure, the guardians of morality and setting the standard of private virtue. For nearly five years organized efforts for the reformation of female drunkards have been made here, and innumerable methods and systems have been tried to that end. And if it be asked, With what result? it must sorrowfully be answered, None. All the "cures" which have been so loudly vaunted and so widely advertised have, as was to be expected, proved utter failures; their warmest advocates are singularly reticent in regard to results, and even fanatical temperance reformers now dismiss the mention of them with a significant shrug of the shoulder.

One of our newspapers some years ago opened its columns to the public discussion of the question, Is Marriage a Failure? Whether—to speak in parliamentary style—the Ayes or the Noes had it, I do not remember, nor is the matter of any consequence. Whatever pessimists may say, it is not always a failure; and the following case may serve to show that it is sometimes a brilliant success. Mr. George Glazebrook, a Fellow of the London Society of Antiquaries, has lately published a curious pamphlet concerning a remarkably prolific couple who, during their wedded life, added no fewer than thirty-nine new members to the human race. The story is told by Mr. Glazebrook from the heraldic point of view in which he is specially interested, but it is worthy of note also from the physiological standpoint, as the facts appear to be well authenticated.

In July, 1698, Thomas Greenhill, "chirurgion of London," petitioned the Earl Marshall that, being the thirty-ninth child and seventh son of one father by one mother, he might be allowed a difference in his Arms to be borne by him in commemoration of the circumstance. From the records of the College of Heralds it appears that a grant was made in accordance with the petition. In the grant the worthy "chirurgion" is described as the thirty-ninth child and seventh son of William Greenhill, of Greenhill in ye County of Middlesex by his only wife Elizabeth, Daughter of John Jones of London. He was allowed to bear the arms borne by his father—"scilicet Vert 2 Barrs argent, in chief a Leopard passant or"—with the alteration of "ye Barrs from Argent to Ermine;" and whereas his forbears had borne for their crests in seals and otherwise a "Demi-Griphon" he was allowed to bear "ye same Gules, powdered with thirty-nine Mullets or." The Earl Marshall granted and confirmed "ye said Arms and Crest so differenced as abovesaid" unto Thomas Greenhill "in consideration of his Services to his Grace and his Family." These words show that Greenhill was the professional attendant of the Duke of Norfolk, the Hereditary Earl Marshall of England. The facts set forth in the petition may be accepted as true, as they are supported by a singularly strong concurrence of proof. Thomas Greenhill based his petition on a statement which if untrue could easily have been disproved by the Herald through whom he presented it, who was well acquainted with his family. The Earl Marshall knew Greenhill well as his chirurgeon, and by ordering the thirty-nine Mullets to be placed on the Crest was clearly willing to testify to the truth of the statements made in the petition. Moreover, it may safely be assumed that the Kings of Arms, as the Chief Heralds are styled,* jealous of the honor of the Earl Marshall and their own dignity, took care to satisfy themselves as to the truth of statements as to contemporary matters, which, if false, could so readily have been dis-

*Readers of Scott will doubtless remember the lines:

And still thy verse hath charms
Sir David Lindsay of the Mount,
Lord Lyon, King of Arms.

proved. Thomas Greenhill was the author of a treatise entitled, "ΝεκροκΗδεια, or the Art of Embalming, wherein is shown the right (*sic*) of burial, the funeral ceremonies, and the several ways of preserving the dead bodies in most nations of the world, etc." It forms a quarto volume which was published in London in 1705.

THE TWENTIETH ANNIVERSARY OF THE FOUNDATION OF THE PHILADELPHIA NEUROLOGICAL SOCIETY.

To the Editor of the Medical News:

Dear Sir: The Philadelphia Neurological Society celebrated the twentieth anniversary of its foundation on January 26 and 27, 1904, with a special scientific meeting at the hall of the College of Physicians, of Philadelphia, and a dinner at the University Club. On the first evening papers were read by Dr. James Hendrie Lloyd, on The Psychological Conception of Insanity; by Dr. S. Weir Mitchell, on The Mental Processes by Which the Rest Treatment Was Evolved; by Dr. J. Chalmers DaCosta, on The Place of Surgery in the Treatment of Insanity, and by Dr. Francis X. Dercum, on Mystic Medicine.

At the dinner, the President, Dr. Hobart A. Hare, acted as toastmaster. In calling upon Dr. S. Weir Mitchell he paid a glowing tribute to one who had illumined the science of medicine and who had contributed to the resources of medical practitioners all over the world an invaluable therapeutic measure which had accomplished more good than any other single plan of treatment in the whole range of therapeutics. Dr. Mitchell responded to the toast "The Dawn of American Neurology" and showed how the Civil War in America furnished the material from which the first systematic studies were made on the Injuries and Diseases of the Nerves. Entering the United States Army as an Acting Assistant Surgeon he was assigned to duty in a large general hospital near the site of the Broad Street Station of the Pennsylvania Railroad, in May, 1863. Dr. William A. Hammond, who was then Surgeon-General, ordered Dr. Mitchell and Dr. George R. Morehouse to take charge of a hospital for soldiers suffering from nervous diseases and transferred them to a hospital on Christian Street and later to one on Turner's Lane, where Dr. W. W. Keen and Surgeon Charles H. Alden, U.S.A., were associated with them. Dr. Mitchell paid a tribute to the wisdom of Dr. Hammond in giving them unusual facilities for observing almost every conceivable type of nervous disease and of injuries of the nerves occurring through two or three years, and these studies formed the basis of several papers on neurological subjects by Mitchell, Morehouse and Keen. Dr. Mitchell said that Dr. Keen could not be killed by overwork, but that he unfortunately turned from the higher branches of neurology to the lower domain of that of a distinguished surgeon.

Dr. Spitzka was introduced to respond to the toast "Neurology in New York," and the toastmaster referred to his studies on the Mid-Brain. Dr. Spitzka said that he stood in the mid of brains. He also referred to Dr. Hammond's work for American neurology, that but for him it would not be what it is to-day in this country. He referred to the social occasions which accompanied the early meetings of the New York Neurological Society, and the brilliant gatherings which marked the origin of the American Neurological Association. He referred to Jewell, Edes and Putnam, of Boston, to Miles and Van Bibber, of Baltimore, to Bannister, to Schmidt, of New Orleans, an indefatigable worker in the anatomy of the brain and who produced some of the most remarkable and perfect microscopical sections ever shown. He spoke of the practical school which was devoted to studies of spinal irritation and neurasthenia; of the Seguin School devoted to the exact science of disease, but permitted the absence of the imagination. The Philadelphia neurologists were referred to in complimentary terms and credited with having had a biological way of thinking. To Leidy we owe a debt, which, in his estimation, was equal to that we owe to S. Weir Mitchell.

Dr. G. L. Walton, of Boston, was introduced as one who believes in making a distinction between a degenerate and a normal man and who has suggested that we henceforth call them deviates. Dr. Walton replied to the toast "American Neurology of To-day," and spoke of the advance which neurologists had made since the days when they devoted themselves largely to moving the poles of an electric battery up and down the body, to advances in our knowledge of myelitis and in other fields. He presented greetings from the Boston Society for Psychiatry and Neurology and referred to the Philadelphia Neurological Society, which had so long stood in the forefront of neurology in this country.

Dr. Wharton Sinkler was then introduced to reply to the toast "The Relation of Medicine to Neurology" and characterized as a man who combined the functions of a successful general practitioner with that of a specialist in nervous disease. Dr. Sinkler said that the relation of Neurology to General Medicine was now that of an overgrown child; that the late Dr. William Hunt had once said that specialists had so divided the general practice that there was nothing left for a new specialist but the umbilicus. He referred to the fact that frequently gross brain lesions were mistaken for hysteria and insisted on the great value of a thorough knowledge of general medicine in the proper equipment of the specialist in nervous disease.

Dr. Charles K. Mills was introduced to respond to the toast of "Neurology in Philadelphia." He reviewed the work of the Philadelphia neurologists, when great activity began to be shown, and referred in passing to the earlier work of Hughlings Jackson, Hitzig, Matthias Duval, and others abroad; to the stimulus which Dr. S. Weir Mitchell imparted to Dr. Mills and others in arousing an interest in the subject in Philadelphia. Dr. Mills said that as a result of these efforts Dr. H. C. Wood was appointed at first a lecturer on nervous diseases in the University of Pennsylvania and was made professor in 1872, the first appointment of the kind in this country, although Dr. Benjamin Rush had previously lectured in the University on Insanity and lectures on the same subject had been delivered by Dr. Isaac Ray, in Jefferson Medical College in 1871-2. Later Dr. Dercum was made Clinical Professor of Nervous Diseases in Jefferson Medical College in 1892; Dr. Mills was made Professor of Medical Jurisprudence and Insanity in the University and Dr. Wolff, Dr. Burr and Dr. Pearce had received other appointments in the colleges. The notable work of the Orthopedic Hospital and Infirmary for Nervous Diseases was referred to, beginning in 1867-8 and growing to a great hospital. The early history of the creation of nervous wards in the Philadelphia Hospital was sketched, growing from 20 patients in 1877 to the wards to 350 patients at present. Then the origin of the Philadelphia Neurological Society was given. At the first meeting in Dr. Mills' office when Dr. Sinkler, Dr. Dercum, Dr. Lloyd and Dr. Eskridge determined to issue a call, and in January, 1884, the first meeting was held at the College of Physicians.

In the twenty years of the Society's existence there have been 616 contributions, including 250 formal papers; about 40 minor scientific contributions and 250 clinical cases presented. Most, if not all, were of a

character to stimulate interest in neurology. The work of Mitchell, A. J. Parker and others too numerous to mention were commented upon and a graceful tribute was paid to the neurologists from other cities who had frequently visited the Society and contributed to the proceedings. G. H.

SOCIETY PROCEEDINGS.

THE WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, held at Denver, Colo., December 28 and 29, 1903.

(Continued from Page 383.)

Mutiple Loose Bodies in the Knee-joint.—Dr. John P. Lord, of Omaha, Neb., reported the case of a middle-aged man who had suffered from recurrent attacks of arthritis, the result of loose bodies in the knee-joint. The attacks of inflammation and the frequent incapacity resulting therefrom had driven the patient to seek operative relief. Loose bodies in the posterior part of the joint were the chief offenders, and it was thought that no ordinary incision would permit of their successful removal. The writer's attention having been called to the use of the Volkmann incision by the Mayo brothers for suppurating knee-joint, it was determined that this method of attack would be required in this case. Transverse division of the patella and the incision of the lateral and crucial ligaments were therefore done, as in an operation for resection. This permitted full command of the articulation. Great difficulty was encountered in removing two of the bodies located behind the condyles. The patella was wired. The capsular ligaments were sutured with chromicized gut. Drainage was instituted and an interrupted plaster dressing applied. Union was primary, and a good result secured, although motion was limited. After two months the degree of flexion amounted to about thirty per cent. Attention was called to the necessity of delaying manipulation after this procedure for fear of retearing of the immature union of the ligaments, thus rekindling the arthritis. After a period of two months, however, active efforts were made to restore function, with greater success, although it was probable that full function could not be regained after such extensive surgical trauma of disarticulation. No precedent in literature was found for so radical an operation for this condition. There were ten of these loose bodies of large size, and so distributed that the ordinary incisions recommended would have been ineffective in securing the bodies, part of which were attached by pedicles. Less radical means would have defeated the object of the operation, and the patient's relief would not have been complete.

Chronic Adhesive Sclerosing Peritonitis.—Dr. H. G. Wetherill, of Denver, Colo., read a paper on this subject, in which, after reporting an interesting case at great length, he presented the following points: (1) The rareness of the disease. (2) Failure to generally recognize and to fully describe it on this continent, though it had been long well-known abroad. (3) The pathognomonic sign, namely, inability to unite the shrinking peritoneum when once divided during the course of the operation, which, so far as the writer was aware, he was the first to observe and describe. (4) The essential chronicity of the disease, as indicated by longstanding symptoms, otherwise unexplained, and by the shrinking and retraction of the peritoneum at the first operation, sixteen months prior to the patient's death, which proved the previous existence of the malady, and that it was not directly or indirectly the result of the operation. (5) The great importance of covering all denuded surfaces when, before or during the operation, chronic adhesive sclerosing peritonitis was diagnosed. (6) The characteristic subperitoneal connective tissue hyporplasia which was the pathologic feature of the disease. (7) The shrinking or contraction of the peritoneum caused by it, the clinical feature. (8) The possible significance of a somewhat similar pathological process taking place in the skin, coincident with unusual gastro-intestinal symptoms otherwise unaccounted for. (9) The danger of serious sequelæ incident to its surgical treatment. (10) The possibility of accomplishing much through medicinal measures, when the etiology of the disease was better understood. Potassium iodide and inunctions of mercury were worthy of careful consideration and trial in any suspected case of plastic peritoneal sclerosis.

Median Perineal Prostatectomy.—Dr. George E. Goodfellow, of San Francisco, Cal., had operated by the median perineal route in cases of hypertrophy of the prostate approximately 73 times, without any immediate mortality, so far as he was aware. He described the technic of the operation in detail. All of these operations were done under spinal anesthesia. Recently he had modified the operation a little. Instead of making an incision, as he had previously described in his papers, from the base of the scrotum to the margin of the anus, he now made an incision an inch in length above the perineal center, and through this opening he could enucleate the prostate with his forefinger. If it was necessary to enlarge the opening, he did so in the usual way. But through an ordinary incision he had enucleated a prostate weighing 7½ ounces. In no case had he failed to secure anesthesia when he had entered the canal. The needle was inserted between the second and third lumbar vertebræ.

Complications and Sequelæ of Prostatectomy.—Dr. James E. Moore, of Minneapolis, stated that no single operator had had sufficient experience to enable him to speak authoritatively upon the subject, and such extremes of experience had been reported that it was difficult to estimate the real dangers and difficulties of prostatectomy. It was altogether too grave an operation to be resorted to as a routine treatment for enlarged prostate, and was only applicable to properly selected cases. There would always be a place for palliative measures in neglected cases of prostatic enlargement. The most frequent cause of death following this operation was uremia, consequently the most important preliminary examinations were those of the kidneys. The next greatest danger was sepsis, and in the presence of an infected bladder it was an ever-present one. Positive indication for operation was very often a complicating cystitis, and it was for the relief of this complication that the various palliative measures were most frequently employed. The only satisfactory treatment for this complication was drainage, and this was best brought about by perineal prostatectomy. Stone was a frequent complication of enlarged prostate, and should always be sought for and removed during the operation. The incision for a prostatectomy, when too extensive, caused various complications. Hemorrhage was an occasional complication, but its dangers had doubtless been overestimated. A serious objection to the suprapubic operation was the extensive injury done to the bladder; while the most difficult problem connected with the perineal operation was how to avoid injury to the rectum. As sequelæ of prostatectomy, he mentioned impotence and incontinence or dribbling. A communication between the urethra and the rectum was

one of the sequels met with occasionally. Epididymitis was quite a common sequel of prostatectomy, sometimes becoming so troublesome as to require the removal of the epididymis. Because the writer had dwelt briefly upon possible, as well as probable, complications and sequelæ of prostatectomy, he did not wish to be classified as a pessimist. Some failures were bound to follow this important operation, as they did every operation of like magnitude. But notwithstanding this fact, it was destined to be one of the greatest boons modern surgery had to offer suffering mankind.

The Use of Silver Foil to Prevent Adhesions in Brain Surgery.—Dr. M. L. Harris, of Chicago, said the general principle of the introduction of some foreign substance had been tried in a sufficient number of cases of brain surgery to prevent adhesions, and with results which seemed to justify a belief in its efficacy. Of the materials thus far proposed, the author believed the thin foils were the best, and of these he preferred the silver foil. It was thin, soft and smooth. It conformed to all irregularities of the surface on which it was laid. As many layers might be applied as necessary to secure a smooth, unbroken surface. It was not only tolerated very kindly by the tissues, but exerted a beneficial influence on granulating or healing surfaces. The foil might be placed directly in contact with the brain tissue between the pia and dura, or wherever it might be necessary to accomplish the purpose desired. The author had used the silver foil in a number of cases of brain surgery, and urged its more frequent use. He cited a case which illustrated the principle.

Resection of Arteries and End to End Union: Experimental Research.—Dr. O. Beverly Campbell, of St. Joseph, Mo., detailed 40 experiments on animals, in which different methods of operating were adopted. The author stated that from a recognition of the probably correct theory of the coagulation of the blood, and considering the experiments that had been made and the results obtained, eliminating the process of infection, there still remained factors in the production of thrombosis in the suture of arteries yet to be met and overcome before it could be hoped to re-establish permanently the circulation of the blood following end to end union of arteries. The possibilities of permanently re-establishing the circulation of the blood in arteries following end to end union, or resection, was in the author's opinion yet to be demonstrated.

In the experiments of Murphy, as well as the writer's, it was observed that where thrombosis did not occur, in the majority of cases an obliterating endarteritis occurred. Murphy observed: "After suture of a vessel there is a tendency to endarteritis obliterans." As this process was one of slow formation, it was one of minor importance as to the ultimate result of arterial suture. While the endarteritis was occluding the vessel, collateral circulation was being established, and the danger of death of the part obviated.

Conclusions.—1. The death of the endothelial cells following injury to arteries and the addition of cell death incident to the trauma inflicted from operative measures for the repair of the injury probably furnished the necessary nucleo-albumin needed for the production of the chemical process of coagulation of the blood. 2. That in the resection of arteries and in their suture in continuity, the suture should not penetrate the intima, as the additional death of endothelial cells incident to passing the suture and surrounding it from pressure necrosis might contribute to the coagulation of blood. 3. That the most rigid aseptic technic should be followed in surgical work upon the arteries.

Surgical Treatment of Pulmonary Abscess.—Dr. Van Buren Knott, of Sioux City, Iowa, stated that in two cases which he had seen, although the patients presented all symptoms common to pulmonary abscess, and the physician in attendance, as well as himself, were satisfied of its existence, they were only able to locate it in one case at the autopsy, and in the other suffered the indignity of having the diagnosis confirmed and failure to locate the abscess accentuated by its rupture into the pleural cavity, with empyema as the penalty. While in many quarters attempts to locate the abscess by aspiration had been denounced as unsafe, and injudicious, his limited experience had taught him the inadvisability of attempting to open an abscess of the lung without the aspirator as a guide. The physical signs common to this condition in many cases were alone not sufficient to render its exact localization possible, and while one might be satisfied in a given case that the lung contained an abscess, and from the usual methods of examination had decided as to its location, this point should be corroborated by the aspirator before proceeding with the operation. Two cases of pulmnary abscess were reported. As to the treatment of these cases by other than surgical methods, the author said it promised little, and as the complications of gangrene, empyema and bronchiectasis so seriously increased the mortality, even in the hands of the best operators, it would appear that a plea made for early operative relief of patients suffering with pulmonary abscess was not inconsistent with the facts.

The Anatomy and Physiology of the Peritoneum and Their Relation to the Treatment of Peritonitis.—Dr. Arthur E. Hertzler, of Kansas City, Mo., said the stomata were declared to be artefacts, for the reason that they occurred only when the peritoneum was treated with a silver nitrate solution. They did not appear when dilute solutions were injected into the peritoneal cavity of the living animal. Other reasons had been given in a previous paper. Attention was called to the fact that the universal reference to the deposit produced when a serous membrane was treated with silver as an albuminate of silver was an error. No such substance existed. What was formed was in all probability a silver chloride produced by the action of the Cl in the fluid with the Hg in the silver solution, producing the stable silver chloride. The peritoneum was covered by a layer of fat cells resting on a layer of elastic tissue. Below this were the blood and lymph vessels. Both systems always formed complete channels, and the lymph vessels never formed a connection with the peritoneal cavity. In the process of absorption from the peritoneal cavity the fluid must pass between the endothelial cells lining the peritoneal cavity, through the elastic layer, and between the cells lining the blood vessels. Whether the cells of each of these layers were united with the intercellular bridges could not be stated. The absorption of 7-per-cent. NaCl solution took place more rapidly than any other solution. Salt solutions of more than one per cent. were absorbed more slowly. Certain solutions caused a transudation, instead of being absorbed. Chief among these was formalin. It was effective in a dilution of 1 in 10,000. Absorption was likewise lessened by the production of an artificial hydremia. Normal NaCl solution might be used either by hypodermoclysis or per rectum, the former being the more rapid and more certain.

Applying these researches to the treatment of peritonitis, the fallacy of normal salt irrigations was insisted upon. By using this fluid the toxins were hurried into the circulation more rapidly. The logical treatment was to employ those means which retarded absorption. The production of an artificial hydremia might be accomplished either by the injection of the salt solution under the skin or per rectum. Formalin in the strength indi-

cated was safe, as had been previously determined by intravenous injections.

Cholecystitis, with Special Reference to Etiology and Diagnosis.—Dr. T. E. Potter, of St. Joseph, Mo., after reviewing the subject, said that the most probable cause of infection of the gall-bladder was not through the intestinal walls, nor through the hepatic tissue, nor from the duodenum through the hepatic ducts, but through the blood of the portal system; and from this source we not only had the catarrhal and parenchymatous inflammations, with occasionally empyema, but sometimes malignancy caused by the presence of stones. Among the most prominent symptoms he mentioned tenderness immediately under the ninth intercostal cartilage, saying that this symptom was as valuable as tenderness in the region of McBurney's point in cases of appendicitis. This tenderness might extend down for two or three inches. To elicit it, one should press the fingers up under the ribs and require the patient to take a deep inspiration. The patient would complain of pain, and if the fingers were held firmly, the act of inspiration was instantly stopped as though there had been a sudden attack of pleurisy.

The Treatment of Posterior Perforations of the Fixed Portions of the Duodenum.—Dr. J. E. Summers, Jr., of Omaha, Neb., read a paper on this subject. Retroperitoneal perforations of the duodenum were of such infrequent occurrence that little attention had been directed towards their treatment. After a careful study, he had been unable to find anything written upon the subject that was at all satisfactory. After referring to the surgical work of Kocher, Villard, Jaboulay, Henle, Jeannel and Mikulicz, the author reported a case of gunshot wound involving the anterior wall of the upper vertical portion of the duodenum and the posterior wall of the duodenum nearer the lower angle. A young man, in attempting to escape from a policeman, was shot in the back by a 38-caliber Colt's revolver, the ball entering one inch below the twelfth rib and through the outer edge of the erector spinæ muscles, coming out in front 1½ inches below the juncture of the ninth right costal cartilage, with the right rectus muscle. One hour after the shooting the patient was etherized; the abdomen was opened by a vertical incision through the wound of exit. It was observed that the bullet had in its course from behind forward perforated the duodenum and gall-bladder. The wound in the anterior duodenal wall was sutured, likewise both holes in the gall-bladder. Because of the bad condition of the patient, it was decided not to attempt to expose the posterior duodenal wall from in front, but rather to rely temporarily upon an incision from behind, and the introduction of the gauze pack. In the carrying out of this latter procedure the writer discovered that the bullet had made a groove through the lower pole of the right kidney, another reason for the posterior incision. A liberal gauze pack drain was introduced down to the repaired duodenal wound of exit, and the wounds of the gall-bladder, and the abdomen closed so as to admit of the drainage. The patient died three days later, the post mortem illustrating the cause of death to be a retroperitoneal phlegmonous inflammation without peritonitis. Had the man's condition permitted, the author would have sutured the wound in the posterior duodenal wall after freeing and rotating the duodenum to the left. In the light of today one should, in a like case, in addition to repairing the duodenal wound or wounds, occlude the pylorus by means of a purse-string stitch. Either at this same operation or as soon thereafter as reaction permitted, a gastro-enterostomy should be made. None of the procedures which he had indicated required much time for handling of the intra-abdominal contents. They were the only rational methods of treating a perforation of the posterior wall of the duodenum. It was almost impossible for a gunshot wound of either the stomach or duodenum, which perforated both walls, to be limited to those organs. Therefore, under such circumstances, in addition to the repair of any intraperitoneal organs involved, proper incisions must be made to provide for retroperitoneal drainage.

Officers.—The following officers were elected: President, Dr. Charles H. Mayo, Rochester, Minn.; First Vice-President, Dr. H. D. Niles, Salt Lake City, Utah; Second Vice-President, Dr. L. L. McArthur, Chicago; Secretary-Treasurer, Dr. B. B. Davis, Omaha, Neb.

Milwaukee, Wisconsin, was selected as the place for holding the next annual meeting; time, Dec. 27 and 28, 1904.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Annual Meeting, held at the New York Academy of Medicine, January 11, 1904.

The President, Andrew H. Smith, M.D., in the Chair.

Election of Officers.—The following officers were elected: President, Dr. T. E. Satterthwaite; Corresponding and Statistical Secretary, Dr. F. C. Raynor; Chairman for the Borough of Queens, Dr. N. O. Fitch; Member of the Executive Council, Dr. S. G. Cook. It was announced that the Council had appointed Dr. J. Lee Morrill, treasurer, in the place of the late Dr. A. D. Ruggles.

Membership.—The annual report of the Corresponding and Statistical Secretary showed that there are now on the roll of the Association 677 Fellows, 100 having been added during the past year.

Synchronous Ureter Catheterization.—Dr. F. Tilden Brown gave a very successful demonstration of synchronous ureter catheterization on the male subject, by means of his improved composite cystoscope. He also presented his first cystoscope, introduced in 1899, and stated that his cystoscope was the first to be employed for the purpose named.

The Bladder in Health and Disease, as Demonstrated by the Cystoscope.—Dr. Henry G. Spooner read a paper on this subject. He first gave a résumé of the history of modern cystoscopy since Nitze in 1879 had introduced a method of directly lighting the bladder by means of an electric lamp. After briefly describing the instruments now in use he stated that the New York Post-Graduate is the only medical school in this country where any practical instruction in cystoscopy is given. It is commonly asserted, he said, that after eight or ten lessons, the student will have acquired sufficient skill to catheterize the ureters, but this is an erroneous impression. Out of 12 men who completed Casper's course during the past autumn, only two succeeded in catheterizing a ureter, and one of these had been a former pupil of Dr. Spooner. Since Fenwick's work, issued in 1889, there has been no text-book on cystoscopy published in English. Only after continuous effort and a broad understanding can judgment be formed for the proper selection of cases for a cystoscopic examination. Before attempting to use the cystoscope on the living bladder the student should practice on one of the phantom bladders now obtainable, or, what will answer just as well, an apothecary's mortar lined with beeswax, to which little pieces of colored sponge are attached. Practice on the cadaver is unsatisfactory, for the reason that the urethral walls have lost their elas-

ticity. The cystoscope tolerates high temperatures very poorly. Having mentioned the methods employed by various authorities to render the instrument aseptic, he said that though the cystoscope is absolutely surgically clean, the urethra is very rich in bacteria. When a lubricant composed of glycerin-tragacanth with the addition of a 1 to 500 solution of *hydrargyrum oxycyanatum* is used, the instrument is said to convey no microorganisms into the bladder. To prevent any possibility of infection the bladder is washed out after each examination with a 1 to 5,000 solution of mercuric cyanide. Casper uses as a routine matter a four-per-cent. solution of cocaine as an anesthetic, and Nitze prefers a similar solution of eucaine, as safer. The bladder is then filled with a two-per-cent. solution of boric acid, and the cystoscope is introduced into the bladder with the greatest possible gentleness, to avoid any trauma of the urethra, which must be of sufficient calibre to permit of the easy passage of a soft rubber catheter 21 to 25 F. For a successful cystoscopic examination the bladder must be tolerant enough to retain at least 60 c.c. of fluid. When the bladder has been distended to the extent of 150 c.c., the cystoscope is inserted until the beak lies in the middle of the vesical cavity. The lamp being then illuminated, a clear luminous field of vision of a light yellow color can be seen. If the bladder is dilated with urine, the picture is more deeply yellow. The knob of the handle of the cystoscope indicates the position of its beak. As the shaft of the instrument is elevated, lowered, moved laterally, or rotated, all the internal surface of the bladder, with the exception of a small portion of the posterior surface, can be seen with the No. 1 cystoscope of Nitze. With the beak pointing up, the instrument is gradually drawn toward the operator, when a darker zone, representing the neck of the bladder, extends across the lower part of the field of vision. If the cystoscope be further retracted, this darker zone increases in size until it covers one-half the picture. On still further retraction, darkness ensues, as the prism has been covered by folds of the prostatic urethra. Before any additional examination is made, the light must be turned off, and the beak reinserted into the middle of the cavity of the bladder. When the cystoscope is pushed back, so that the prism is focused on a surface of mucous membrane, a pale pink field, shading on the orange, with parallel arterial branches, is seen in the normal bladder. The color of the healthy bladder varies, however, with the individual and with the locality of the bladder in the same individual; also with the brilliancy of the illumination, the distance of the prism from the bladder-wall, and the transparency of the fluid medium. When the beak is rotated below 1908 and moved forward and backward, there can usually be distinguished the interureteral line, which represents the posterior boundary of the trigonum. This line is a very important landmark, as the ureteral orifices can be found at its lateral termination. When the bladder is not sufficiently distended, the folds of mucous membrane of the trigonum will prevent the interureteral line and the ureter openings from being seen. When the prism is placed directly on the ureteral orifice, the latter is observed as a luminous line in the form of a slit, which is generally located on an elevation. At the moment when drops of urine exude from the opening the ureter can be seen to bulge on the surface of the vesical wall. While the ureteral orifice is usually situated on a little round protuberance, it may lie in a depression. Its form is materially altered after cystitis and also after some constitutional diseases. Just when the variations of the normal bladder have advanced to a sufficient degree to constitute a pathological condition is often difficult to determine. When there is any hindrance to micturition, the muscular framework of the viscus must do more work than formerly. Slightly trabeculated bladders are found both in youth and old age, and cannot be considered pathological. In cases of urethral stricture or prostatic enlargement the bladder hypertrophies more and more, in consequence of its efforts to expel its contents, until we meet with a markedly trabeculated condition. As the intravesical pressure is increased, the urine is forced in between the trabeculæ, and pouches, not infrequently of considerable size, become formed. In extreme cases a rupture of the bladder, with fatal peritonitis, may result.

Its Use in Cystitis.—In cases of cystitis it is generally stated that the cystoscope is contraindicated on account of the intolerance of the bladder. With patience and perseverance, however, all the details of the inflammed bladder can be studied cystoscopically, the dilated arteries, the swollen and deeply congested mucosa, and here and there extravesations of blood or surface ulcers. The cystoscope has shown that gonorrheal cystitis is a localized process, involving the neck of the bladder and the trigonum, but never extending any further. More frequently than was formerly supposed, cystitis tuberculosa is engrafted in the chronic gonorrheal area. Miliary tubercles can be seen in the form of small round gray elevations, surrounded by hyperemic areas. Later, extensive ulcerations of the mucosa and submucosa are formed. After inflammation of the bladder, especially the gonorrheal variety, the region of the trigonum shows a remarkable tendency to papillary proliferation. The deeper layers of the polymorphus epithelium of the trigonum are of considerable interest, inasmuch as the spindle-shaped and cylindrical cells have much similarity with isolated elements of certain malignant growths. From the histological formation of the trigonum it is therefore easy to understand why this region should show such a tendency to papillary proliferation. As growths of the bladder increase in size for a long time without causing the patient any suffering, an early diagnosis can be secured only by means of a cystoscopic examination. These small villous growths are the starting points of most of the tumors of the bladder. Single growths with small pedicles are mostly benign, while tumors having a broad base are generally malignant. In cases of vesical calculus a cystoscopic examination will give us an exact knowledge of the existing conditions. Small concretions may be overlooked, and the cystoscope may reveal their presence. To determine the extent of mechanical hindrance to urination occasioned by hypertrophy of the median lobe of the prostate, the cystoscope is our only guide. Dr. Spooner's paper was illustrated by a large number of diagrams, accurately colored, representing the various conditions described.

The Cystoscope Not of Universal Applicability.—Dr. Frederic E. Sturgis said there were many instances in which the cystoscope was of very little service. This was especially the case when hemorrhage was present.

Asepsis. The usual agents employed to secure asepsis, carbolic acid, formaldehyde, etc., were objectionable because if used in sufficient strength to be of service for this purpose the solutions must be stronger than safety admitted. He thought the best things to employ were hot water, alcohol and soap. The water should not be too hot, however, as this would prove injurious to the cystoscope. It was impossible by any method to obtain complete asepsis, and, at all events, he believed that most of the bacteria (about which we really know very little) were less deleterious than was generally supposed. In his opinion the procedures usually advocated, such as syringing the urethra thor-

oughly, injecting the bladder, and giving urotropin as an internal urinary disinfectant, were productive of more harm than benefit. There was nothing better as a lubricant than sterilized oil.

Anesthetics.—He objected to the use of cocaine, first, because in irritated conditions of the mucous membrane it might prove dangerous, and, second, because by depleting the mucous membrane of blood it gave rise to misleading appearances of the parts. Again, the pain which occurred after its effects had passed off was apt to be more severe than if no anesthetic had been employed. As to eucaine, this was absolutely worthless.

Amount of Fluid Required in the Bladder.—There should be five or six ounces of fluid in the bladder, if the patient could stand it; in fact, the fuller the bladder, the better, as the maximum distention possible was desirable.

Only Recently the Cystoscope has Proved of Practical Service.—Dr. Eugene Fuller said that although the cystoscope had been known for a number of years, we were now able to do much more with it than formerly, on account of the improved apparatus at our command. Thus, the introduction of the cold lamp had really revolutionized the use of the instrument. Burns had frequently resulted from the hot lamp, and it was always a source of danger and anxiety. Again, ureter catheterization was almost entirely impracticable with the older cystoscopes, while with Dr. Brown's improved apparatus it could be easily done. All that was needed was a good eye, a steady hand, and good judgment as to where to look for the ureter orifices.

Air Cystoscope.—The air cystoscope of Dr. Lewis, of St. Louis, is of great service in cases where the bladder cannot be distended, but it is not of very wide applicability. In order to employ the cystoscope with advantage a good deal of practical study is required, and facilities for becoming familiar with its use are now afforded in this city.

Hemorrhagic Conditions.—Dr. Sturgis had spoken of the small utility of the cystoscope in conditions with hemorrhage. He thought, however, that by means of the adrenalin extracts we could usually now get rid of hemorrhage and obtain a good view of the parts. The cases presenting the most difficulty were those in which the hemorrhage comes from the anterior portion of the urethra and where the passage of the instrument itself excites hemorrhage.

Prostatic Hypertrophy.—As regards prostatic hypertrophy, he had never been able to derive much benefit from mapping out existing conditions before operating. The cystoscope was an excellent instrument in its place, but we could not do everything with it.

Facilities.—Dr. Ramon Guiteras said that in using the cystoscope the more elaborate tables were naturally the best, and the one which Dr. Brown had shown in making his demonstration certainly left nothing to be desired. For all practical purposes, however, an ordinary operating table served very well. Glycerin was the best lubricant, and to secure asepsis he was in the habit of employing the formaldehyde sterilizer. Cocaine could be resorted to if necessary, but in most cases the cystoscope could be used without it. From five to ten ounces of fluid in the bladder were the most satisfactory quantity. Certainly nothing had done more for modern cystoscopy than the substitution of the cold for the hot lamp. Under its use the patient suffered far less during manipulation and examination.

Different Cystoscopes of Service.—There is a variety of cystoscopes, and the operator should be able to use different ones as occasion required. Thus, for women the straight cystoscope was the best. The air cystoscope could not be compared with the water instrument as regards general utility. Practice, patience and perseverance were required for the skilful use of the cystoscope, and particularly in catheterization of the ureters. Especially was this the case as regards the air cystoscope.

A Simplified Cystoscope.—Dr. Follen Cabot presented a simplified cystoscope which he had devised. It was provided with but a single telescope, and was less expensive than the more elaborate instruments. He said it could be used with air as well as a solution. Air, he had found, was a little more painful.

Roentgen Rays in the Treatment of Cancerous and Skin Affections; Roentgen Rays in the Treatment of Epilepsy; Roentgen Rays in Diagnosis.—This was the title of a paper by Dr. J. Herman Branth. He said he desired to speak frankly of his own personal experience, which might vary somewhat from that of others. Instead of indulging in theories and scientific speculations, he would direct attention to practical points and to facts which he had observed again and again. He had to confess that he was not yet entirely rid of a certain skepticism as regards the remedial value of the X-rays which he had very strongly when he began to work with them. This agent was certainly not a panacea, and he hoped that due conservatism would prevail in the profession. Well tried remedies should not be lightly cast aside for the new and untried. At the same time, it was a fact that electricity, in one form or another, had gained a position as a remedy in affections in which heretofore, notwithstanding the pharmacological and surgical resources at our command, we had been helpless. In malignant disease the results with the X-ray are variable. The deeper the cancer, the greater the difficulty of successfully treating it; yet it has been his observation that in nearly all the deeper seated cases (this applies particularly to mammary cancer) the disease comes to a period of rest, further development being stopped for a time. He has not seen one case of cancer of the breast recede into a normal condition under X-ray treatment alone. There always remains a hard or perhaps more or less doughy deposit, and from this, as a focus, any degree of activity may at any time be developed. Consequently, he would not call this condition a cure. In his opinion it would be wrong to indiscriminately displace the knife by X-ray applications. The results when the cancerous tumor is removed by thorough excision, and this followed by X-ray applications, are oftener satisfactory, and he has observed several recoveries from post-operative recurrences as a result of X-ray treatment. It appeared to him that radiotherapy was the most successful in those cases in which the débris could be thrown off directly. If the Roentgen rays had the property of stimulating protoplasm into higher and more healthy activity, this might perhaps afford some explanation of the results observed not only here but in epilepsy. For epithelioma, rodent ulcer, lupus, and some other skin affections the X-rays prove an almost certain remedy. Dr. Branth here presented a private patient, a lady who had had lupus for fifteen years. All this time the best skill of prominent medical men was of no avail, the disease steadily progressing. A photograph was shown of her face when she applied to Dr. Branth for treatment. It was a remarkable result of the X-ray applications that a good part of the disease-invaded tissue was restored or in process of healing. This patient is still receiving one treatment a week. As regards Roentgen rays as a remedy in epilepsy, all cases of the disease are not amenable to this treatment, as, for instance, those in which degenerative processes in the brain have set in. In many instances the occurrence of the seizures

is believed to depend upon the instability of the cellular brain elements, or an abnormal metabolism, and as it is accepted by many authorities that the X-ray stimulates the vital activity of protoplasm, it was on this theory that the treatment was adopted. For the results obtained, Dr. L. C. Vincent deserved at least half the credit. About a year ago he and Dr. Branth together planned the method, but, owing to severe and prolonged illness, Dr. Vincent was personally unable to take part in the practical work. Three treatments per week are given, beginning with five minutes exposure at fifteen inches distance, and gradually increasing to ten minutes exposure and ten inches distance. A hard, or high vacuum, tube is employed, and a different part of the cranium is exposed at each sitting. The hair may drop out in areas, but it is certain to return in a stronger growth than before. In some epileptic patients there seems to exist a bromide drug habit, and to suddenly withdraw the bromides may cause a shock to the system.

In a few instances the best results were secured by returning to small doses of the bromides in addition to the X-ray treatment. With very few exceptions the patients gain in weight at a surprising rate. A lad, fourteen years of age, who was presented by Dr. Branth, had gained 9 pounds in four weeks. At the time the treatment was begun, November 8, 1903, the convulsions (grand mal) were becoming more and more frequent and severe, notwithstanding the free use of bromides. Since the date mentioned he had not had a single seizure, and his mother and his teachers had been astonished at his mental, as well as bodily, improvement. In his case the bromides had been at once withdrawn, and in addition to the X-ray treatment to the head, the static brush had been applied to the spinal region and head. Dr. Branth said he could cite a number of such histories, varying, of course, in different particulars. The gain in weight was noticeable even in those cases in which the mental faculties did not improve so rapidly. In cases of both grand and petit mal it was observed in general that the seizures became lighter and of shorter duration, that the intervals were longer, and that when a seizure occurred it was followed by less prostration than formerly. As to the diagnostic value of the X-rays, the surgeon may be guided by an X-ray photograph with more safety and certainty to give relief, while many patients have already been saved from the necessary danger of an operation because the X-rays demonstrated that an operation was needless. A photograph is far more reliable than a fluoroscopic examination, as it reveals details which are invisible by the fluoroscope. Dr. Branth presented a number of radiographs taken by himself. One was of an arm from which he excised the elbow-joint in 1896. The new false joint is cartilaginous, but there is nearly the normal amount of motion in it. This patient was also presented. One of the radiographs exhibited was taken through the skull of a young man, and demonstrated the value of X-rays in locating foreign bodies in the brain. A short time ago Dr. Branth had read in a medical journal that the X-rays could be used as a certain test for the existence of the life spark. This was proved to be an error by a radiograph which he presented of an Egyptian mummy's hand, dead about 3,500 years. In comparing this with the picture of living hands it was seen that in both the bones showed almost equally well. In the radiograph of a six months' fetus the ossified condition of the long bones was well shown; also the cartilaginous condition of the joints, the cartilage offering no resistance to the X-rays. The radiographs presented nothing new and were of inferior quality.

CHICAGO SURGICAL SOCIETY.

Joint Meeting of this Society and the Chicago Medical Society, held January 13, 1904.

The President, E. Wyllys Andrews, M.D., in the Chair.

The Surgical Treatment of Bright's Disease.—This was the subject for discussion.

The Medical Aspects of Decapsulation of the Kidneys for the Cure of Chronic Bright's Disease.—Dr. Arthur R. Elliott opened the debate. He stated that a study of the statistics available to date showed the total number of cases of true Bright's disease operated upon as 76; died, 36; mortality ratio, 47.36 per cent.; improved, 26; improved ratio, 34.21 per cent.; unimproved, 12; unimproved ratio, 15.78 per cent.; rendered worse, 2; worse ratio, 2.66 per cent. Of the 36 fatal cases, 13 died within the first week and a total of 20 during the first month following operation. He said we were justified in combining the mortality, unimproved and rendered worse ratios, and thereby estimating that 65.80 per cent. of cases operated on in the various forms of Bright's disease failed to be favorably influenced. On grounds furnished by statistics and considerations, the entire class of chronic interstitial nephritis was not adapted for surgical treatment. The only exception to this rule was the comparatively rare circumstance of an acute nephritis engrafted upon a chronic interstitial lesion, in which event the acute inflammatory attack might introduce the necessary element of intracapsular tension. The question of the admissibility of operation in cases of advanced chronic interstitial nephritis was answered by statistics. The mortality (76 per cent.) was almost a prohibitive one, and the chances of prolongation of life much less promising than those which medical treatment held out. Experience to date would seem to indicate that cases of chronic parenchymatous nephritis in young subjects and especially those cases following acute infective nephritis, offered the most favorable material for operation. A study of the statistics of operations in parenchymatous nephritis indicated that a competent heart was the most important consideration influencing the decision to operate.

Dr. Elliott closed by emphasizing the following points: (1) Chronic Bright's disease, in its development constitutes a diseased condition of the entire system. (2) It is a disease of very gradual development, and in the great majority of cases, has existed for months and years before the patient comes under observation. (3) It is produced by a chronic toxemia, either systematic or infective in origin, which produces coincidently as a result, widespread arterial and cardiac degenerative changes, which, being once established, are permanent, and which in their development eventually constitute the most threatening element of the disease. (4) General edema or anasarca in chronic renal disease is in many instances in great measure a cardiac dropsy brought about by advancing myocardial degeneration. It is occasionally so in chronic parenchymatous nephritis, and almost invariably so in chronic interstitial nephritis. (5) It may be stated that in like manner, developing anuria and uremia in chronic nephritis, may be largely cardiac in production, the functional inadequacy of the kidneys having its inception in the fall of blood pressure, incident to circulatory failure. (6) In the later stages of chronic nephritis of whatever character, the case is apt to take on these cardiac aspects which virtually convert the therapeutic problem into a question of sustaining a failing heart. (7) Albuminuric retinitis must be looked upon as one of the terminal symptoms of chronic nephritis. The concordance of opinion places a limit of two years upon the prognosis

after the development of this complication. The statistics of operated cases gathered by Suker, show that in place of prolonging this limit of expectancy, operation has a decidedly contrary effect. (8) It is to be borne in mind that chronic nephritis is a disease of slow and spasmodic development. It is well to realize its exacerbations and remissions, so as to avoid the error of mistaking remissions for cures. (9) The mere fact that the general condition of the patient improves somewhat after decapsulation does not establish the validity of the operation, for hygiene and rest will do the same for the patient to a remarkable degree in many cases. As the factors of hygiene and rest are invariably associated with the surgical procedure, it is possible that the resulting benefit may, to some extent, accrue from those sources. (10) The results of experimentation demonstrate that within a period of three and one-half months after decapsulation a new, and in most cases, a tougher fibrous envelope, has taken the place of the original capsule. This fact may account for the many relapses and deaths after that period in operated cases, and in chronic cases, at least, it narrows the prospect of improvement to a period of months.

A Consideration of the Surgical Treatment of Chronic Bright's Disease from an Ophthalmic Standpoint.—Dr. George F. Suker followed with a paper on this subject.

After presenting and analyzing the statistics which the author had collected from the literature, he summarized as follows: (1) As at least 25 per cent. of all grades and varieties of chronic Bright's disease present evidences of retinal or other fundus complications; and (2) as these fundus complications are usually of the degenerative inflammatory type, attended by like changes in the kidney; and (3) as the cardiovascular system is or shortly will be seriously involved; and (4) as such changes may develop in the fundus without any subjective symptoms on the part of the patient; and (5) as these retinal complications are indicative proof of a general systemic circulating toxin; and (6) as the death rate of this class of patients under medical treatment (hospital and private practice) is about 75 per cent. for the first year, and, at least 85 per cent. for the second year, scarcely any surviving four years, and practically 100 per cent. when operated upon; and (7) as these fundus findings are of paramount prognostic import in an inverse proportion to the age of the patient; and (8) as the medical aspect of this question as presented this evening by Dr. Elliott offers as good, if not better, results than the decapsulation in like cases; therefore, this climacteric array of positive clinical data, which is so palpably available, should not be disregarded on the part of the surgeon in endeavoring to establish the validity of this operation under discussion. Especially so when it can be said that in this class of cases some verily died because of the operaton and others in spite of it, and all fell within the pale of the classic two-year limit, and a larger share died within six months.

Finally, the writer has reasons to believe from the facts above mentioned, that he has conclusively proven decapsulation of the kidney for chronic Bright's disease to be absolutely contraindicated whenever such patients have a retinitis or a neuroretinitis albuminurica, with or without retinal hemorrhages.

Decapsulation of the Kidney for Bright's Disease.—Dr. E. Wyllys Andrews reported four cases of this operation. The first was a man, thirty-two years of age, who had had chronic interstitial nephritis for some years. Double decapsulation was performed, following which there was decided improvement in the total amount of urine passed, as well as solids, and for a period of three weeks thereafter the urea exceeded one per cent. and remained between one to two per cent., while the number of casts was about the same. There was a small amount of albumin in the urine. The subsequent history showed a reduction in the amount of urea again. The patient was watched carefully, and at the end of nearly eighteen months after decapsulation there was very little change for the better, nor yet was the patient worse. In the second case the man had been six months before, and six or eight months after, decapsulation, constantly on the strictest diet, and while he reported himself robust, the urinary findings were about the same as before the operation. The third case was a child nine years of age, whose kidneys were decapsulated under spinal anesthesia. The immediate result of the operation was favorable; but later the patient was as bad as before decapsulation. The fourth case was one of intermittent hydronephrosis and nephritis, and was operated on two months ago. There was relief from all of the symptoms by a combined nephropexy and complete decortication of one kidney, but he thought the nephropexy brought about the relief rather than the decortication.

Dr. A. J. Ochsner said we must look upon cases of nephritis as forming two distinct classes. In the one class we had healthy kidneys, one of which had been injured mechanically, and this injury having been corrected by fixation and decapsulation, the kidney itself contained the elements which were necessary for its recovery. This class was discussed by Edebohls in his first paper. In the other class, with systemic causes, the conditions were different. Tension might depend upon edema of the kidney. It was increased in these advanced cases by the edematous condition of the organ itself. After relieving tension there was a flow of edematous fluid the same as was found in cutting through the remaining edematous tissues. Having relieved edema, it was easy to imagine that the kidney tissues would be relieved of a certain burden, and the tissues which are practically inactive before became active again. But these kidneys did not possess the elements necessary for recovery ordinarily. As regards patients suffering from advanced nephritis he had operated on seven cases which seemed hopeless. All had died with the exception of two. One of them, the last one operated upon, was a man fifty-one years of age, an alcoholic, with marked edema, patient having all the symptoms of advanced interstitial nephritis. While he was still alive, he thought he would soon die. One case corresponded closely to the one narrated by Dr. McArthur. The patient was thirty-six years of age. He was operated upon June, 1903, and at the present time is well. Of the others, five out of seven had died, one of them within two weeks after operation. One improved materially after operation upon one kidney, but died within a week or ten days from acute uremia. Another patient lived for a few months, and then died from uremia. Two were alive, one of them having been operated upon only a few weeks ago. He said sufficient observations had now been made to justify the profession in accepting the conclusions drawn by Dr. Elliott.

Chronic Nephritis.—Dr. L. L. McArthur reported this case, in which he resorted to double decapsulation of the kidneys. Recovery from the operations was uneventful. The final conclusions applying to this case were (1) general condition much improved since operative interference. The element of time and two periods of absolute rest in bed for two weeks each were considered here as possible causative factors, while, on the other hand, be it noted, the patient for over a year before operations was under excellent medical care and given full benefit of diet, hygiene and change of climate.

(2) Distinct improvement in the quantity and quality of the urine secreted from the kidney first operated upon as compared with the unoperated kidney. (3) Improvement in quality and quantity of urine from both kidneys since the operations.

Dr. Alexander Hugh Ferguson said that surgeons should study their cases more carefully and find out what cases were suitable for this operation and those which were not. With an experience comprising over 20 operative cases, he put down the indications for surgical intervention in Bright's disease as follows: (1) He would decapsulate all cases of tender and floating kidneys, and suspend the kidney. He had made inquiries of 13 patients who had been operated upon for kidney trouble, and of this number all but three had been decapsulated, pointing out the fact that the kidney, after it had lost its mobility and interfered with the circulation, produced a low form of renal inflammation which under the microscope proved to be nephritis. (2) He had previously refused to operate upon cases of floating kidneys because there were marked evidences of Bright's disease, but now he considered it an indication for decapsulation. (3) Decapsulation of the kidney was indicated in nephritis itself. He detailed several cases, and expressed himself as believing that there was a legitimate field for renal decapsulation.

Dr. Emil Ries narrated an interesting case of hematuria in which he resorted to decapsulation. At a subsequent operation it became necessary to remove the kidney. The newly formed fibrous capsule along the kidney was about as thick as one's little finger. From the kidney removed over 600 sections were made. He had stained and examined every one of these sections, and among them there was but one anastomosis, and this was near a strip of connective tissue which followed the path made by him in the first operation with his finger, which he inserted into the pelvis of the kidney. Even this was not a direct anastomosis of kidney tissue, but of scar tissue to scar tissue, which was one of the smaller vessels in the capsule. The 600 sections were taken from numerous parts of the kidney. This proved conclusively that the theory of success of this operation (decapsulation), that it might be due to anastomoses forming, was incorrect. After mentioning five cases in which he had resorted to decapsulation of the kidney, he said he was skeptical as to the ultimate results of this operation.

Dr. R. B. Preble said his attention was first called to this subject by a report of two cases which Dr. Ferguson presented before the Chicago Academy of Medicine. At that time he objected on the ground that the cases were reported as symptomatically cured of Bright's disease. The expression symptomatically cured carried with it two implications: (1) The symptoms were there and were the result of the condition; (2) the symptoms disappeared after the operation. It also carried the further implication that the fundamental process which underlay the symptoms was not altered by decapsulation of the kidneys. The symptoms were merely relieved by it. The first case, as he recalled, reported was diagnosed clinically as probably a stone in the kidney, on account of pain in the back. The patient was operated upon; no stone was found; a portion of the kidney was removed, examined microscopically, and showed the microscopic appearance of chronic nephritis. The second case was a patient, who had had, at irregular intervals, elevation of temperature, which was interpreted as being due to infected kidney. Patient was operated on, and no pus was found. A section of the kidney was removed, and the same condition found as in case one. Dr. Preble pointed out in a very forcible manner that pain in the back was not a symptom of chronic Bright's disease, nor was elevation of temperature. These two cases, he said, formed the starting point that decapsulation had relieved these two patients of symptoms which were due to chronic Bright's disease. He said throughout the literature the word nephritis and chronic Bright's disease were used interchangeably. They were not identical terms. The difference between the two was clearly pointed out.

Dr. Arthur Dean Bevan, after reviewing Edebohls' first papers on the subject and pointing out how he had undertaken the operation of renal decapsulation, said he did not think the operation could be said to be the surgical treatment of Bright's disease, because, as a matter of fact, the great majority of surgeons throughout the United States and of the world had never accepted the operation as being a logical procedure. He ventured to say that nine-tenths of the surgeons, who were members of the American Surgical Association, had not accepted renal decapsulation as a logical operative procedure. While he thought credit should be given to Ferguson, Edebohls, and others for working out the problem, the time had come when the profession could safely say that stripping of the capsule as a treatment for Bright's disease was a complete failure, and should receive the stamp of disapproval of scientific men. Out of this work there had come some good, because it emphasized the importance of a class of cases in which another operation was of value, namely in cases of anuria, of essential kidney hematuria, in chronic pyelitis, with some nephritis, draining the kidney by a rapid nephrotomy was of a distinct value. It had effected a great many cures, and would accomplish more.

Dr. Randolph Brunson reported the case of a prominent physician, who presented all the classical symptoms of chronic Bright's disease. Ophthalmoscopic examination revealed typical albuminuric retinitis. After the patient had been treated for eight or ten months without any material improvement in his condition, renal decapsulation was advised as a last resort, reluctantly consented to by the patient, and double decapsulation was made. The patient fully recovered from the effects of the operation, but finally died of Bright's disease.

Dr. Joseph L. Miller said that any one who studied the statistics of Edebohls with a view to obtaining information as to the value of renal decapsulation immediately met with difficulty. The analyses and diagnoses were too indefinite to draw any conclusions as to the value of this operation in cases of nephritis. The profession needed a few cases, carefully studied before and after operation, to settle the question of the value of the procedure.

Dr. Gustav Kolischer thought Drs. Suker and Elliott had struck the keynote, that the value of renal decapsulation was not well established. It was very essential to make diagnoses based upon proper conceptions of pathology. The idea of suggesting decapsulation in a case of floating and tender kidney, or of excising a portion of the kidney, when there were no indications of nephritis, was based upon a wrong conception of the principles of inflammation, especially of renal tissue.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedic Surgery.

Stated Meeting, held January 15, 1904.

The President, Homer Gibney, M.D., in the Chair.

Osteitis of the Left Hip and of Left Fourth Metacarpal Bone. Dr. W. R. Townsend presented this case. The patient was a boy who was first seen on December 19, 1902, at the Hospital for Ruptured and Crippled. The hip has been under treatment ever since

and is getting along nicely. One year ago a swelling appeared on the hand, disappearing after rest. No syphilitic history can be made out. Within the last few weeks the swelling has returned. An X-ray picture was taken three weeks ago, showing that the entire fourth metacarpal bone is involved, and that the disease is confined to that bone. In such a case the entire bone should be removed to prevent spreading of the disease rather than to wait and let it progress and extend to the other bones of the hand.

Typhoid Spine.—Dr. Townsend also presented this case. The patient, a boy aged fourteen years, was seen at the Ruptured and Crippled Hospital, November 23, 1903. Eight weeks prior to that time he had typhoid fever which lasted four weeks. At the end of the typhoid fever he was in fair physical condition. One week after the typhoid he developed pain and stiffness in the back which increased until when he came to the hospital he was bent over very much, suggesting a case of Pott's disease. The pain was not localized but extended up and down the spine. He had no pains in any other region. The patient's physical condition has materially improved since he began wearing a plaster jacket and he now feels so well he is anxious to get it off. Dr. Townsend said he would like to present very briefly the history of two other cases of typhoid spine which he had treated within the last year. The first patient was a girl of eleven years who, after typhoid, began to complain of pain in the spine, especially about the lumbar region. No kyphosis, no deformity whatever, but the entire spine was very stiff. The girl was markedly neurotic. The question was whether it was a typhoid spine or a neurosis. The previous history of typhoid inclined the speaker to that diagnosis—of the type to which Osler refers—a neurosis. Dr. V. P. Gibney, who also saw the case, agreed in the diagnosis. Under a brace she made a good recovery. The second patient was a man. Ten days after the typhoid he was in the Adirondacks recuperating, when he was seized with severe pain in the spine. His pain was so severe, he was moved with the greatest difficulty. Even the attempt to move him from side to side caused the most excruciating pain. He was not neurotic. His face indicated that he suffered intensely. No one vertebra was more prominent than the others; no one spot more painful than another. He complained of pains over the entire lumbar region. A brace was applied, but was kept on only a few moments, as it seemed to increase the discomfort produced by lying on his back. Codeine was given in the hope of quieting the pain and finally hypodermics of morphine were resorted to, and after a week the brace was re-applied and kept on. There was persistent pain over the pelvis on both sides between the hip-joint and the anterior superior spines. Nothing was ever found to account for it. These pains continued for three weeks or more, and persisted after pain in the spine had ceased. No disease of the hip-joint was ever made out, no abscess, neuritis, or anything except that he insisted on the fact that he had intense pain there. Under the use of the brace and rest in bed for six weeks, he entirely recovered. The man now walks about the house, but is very thin and feeble. Does not require a cane or any assistance in walking.

Dr. T. Halsted Myers, in the discussion, said he thought the typhoid spine case showed two characteristic points:—The extreme pain in these cases: He had, this fall, been obliged to chloroform a patient in order to put on a plaster jacket, and chloroform him again to take it off and replace the plaster. The second point was, the prompt recovery, often in one or two months.

Dr. Homer Gibney said he had seen a recent case of typhoid spine in which all the symptoms were referable to the cervical spine. Dr. Whitman had applied a short jacket with jury mast or chin support which elevated the chin, and that this case made an uninterrupted recovery. He had seen a number of cases in which the pain had been intense respond rapidly to cautery and fixation.

Dr. R. Sayre said he had not seen many cases of typhoid spine, but had seen a certain number of them, and had at present a case of scarlatinal spine under observation. The patient, a boy, had been well until he had a severe attack of scarlet fever some three or four years ago. Following that he had nephritis which lasted for a number of months. Then he had what was supposed to be rheumatism in various parts of the body, finally located in the back. When seen by Dr. Sayre, it was discovered that he had large intra-abdominal abscesses and a slight kyphosis. All of these apparently dated from his scarlet fever. Abscesses subsequently opened in one iliac fossa and in the opposite thigh.

Congenital Deformity of the Neck Resembling Torticollis.—Dr. Sayre presented this case. The patient had a certain amount of pain in her neck which ran down toward her arms. Her mother thought deformity had increased somewhat. Examination of the case was extremely difficult by X-ray, as the ear was drawn so close to the shoulder as to make it hard to insert the plate. The plates made were not very satisfactory. When the child's head was well bent to one side, one felt some very hard, solid substance down in the neck, which is either a very long transverse process or else possibly some supernumerary ribs. The distance was very much shorter than it should be between the ears and neck, and the X-ray showed that the upper vertebræ had coalesced.

Dr. J. R. Hunt said he would like to ask how Dr. Sayre excluded an extreme degree of congenital torticollis. The right sternocleidomastoid muscle was practically atrophied, representing only a tendinous cord. The other muscles of the right cervical region were also tense. There was an extreme asymmetry of the face, so often an accompaniment of this condition. Curvature of the spine and rotation of the cervical vertebra would be a natural and inevitable result. Furthermore the skiagrams demonstrated the absence of cervical ribs. The long prominences palpable in the side of the neck would be sufficiently accounted for by subluxation and rotation of the vertebræ, allowing an abnormal projection of the transverse processes.

Dr R. Whitman said that he had seen a case recently very similar to that shown by Dr. Sayre, particularly the same short thick neck with the growth of hair in the median line; the torticollis was less marked. He would suggest as an explanation that the malformation was an incomplete cervical spina bifida, the vertebra being expanded laterally as well as otherwise destroyed. The torticollis was of course an incidental effect of the underlying malformation.

Dr. Sayre said when he first glanced at the patient, he thought it was an ordinary case of torticollis. As soon as he felt the neck, he saw it was not the usual kind of torticollis. There was atrophy of the muscles on one side of the neck and an unilateral lack of development of the face it is true, but in addition to these features, there were bony growths not found in ordinary torticollis. There was great distortion of the upper ribs not found in such cases and there was more rigidity in the neck than that due to shortened muscles —rigidity due to improper movement of the cervical vertebræ. Apparently some of the upper vertebræ have

coalesced. They do not present the ordinary picture of cervical vertebræ. It was an extremely difficult case to examine, on account of the short distance between the ear and shoulder. The child's condition has improved during the past month. It is not practicable to do anything more at present than to give a suspension apparatus and have the child placed in a chair with the head stretched out a reasonable time each day. The child could not be suspended long at a time. It had been suspended a moderate amount, with the neck stretched out, to see if a better skiagraph could not be made after the yielding of the muscles. On a closer view of the anteroposterior skiagraph it looks as if the spinous processes possibly had not coalesced, simply had that appearance from the hunching up of the angle of the ribs on the posterior side. The spinous processes may have been twisted and that might be one of the hard things felt on the side. As to the mane on the back; that is often seen in spina bifida occulta, as is mentioned by the German and French authors. He had seen it but seldom. A boy with lateral curvature, under observation at present, has an extremely heavy mane.

Syphilitic Joint Disease.—Dr. Myers presented this case. H. S., fourteen years old. No family history of tuberculosis or syphilis obtainable. Child had an ozena for four years; fistulæ leading to carious bone in nose two years, and in left elbow one and one-half years. Later, an abscess appeared in parotid region and seven months ago without injury, the left knee became swollen. There was some heat, a little pain at night only, no redness. On admission to St. Luke's Hospital, December 4, 1903, the circumference of the left knee was two inches larger than the right; fluid in the joint and induration about it, with noticeable enlargement of tibial shaft, though it was one-eighth inch short. Marked muscular atrophy of thigh. Flexion from 175 to 80 degrees. No spasm. No pain. Skiagraph showed marked enlargement of tibia and radius and lower end of the humerus, all on left side. A marked keratitis was present and thought by Dr. Cutler to be of specific origin. Specific treatment was instituted at once and the change in the child's condition is remarkable. The swelling of the knee has almost entirely subsided, and the motion increased proportionately. The sinuses in nose and elbow are closing fast and the corneal opacities are less. A tuberculin test January 13, gave a slight transitory reaction which was not considered of diagnostic value.

Pott's Disease.—Dr. H. L. Taylor presented a case of this disorder in which the principal interest consisted in comparing the man's present condition with his condition about five years ago when shown to this section. The man had suffered at that time for several months from excruciating pain in the lower part of the spine and flanks; the pain was so severe he could scarcely move, there was stiffness and very marked cachexia, but no kyphosis. A jacket was applied once or twice but he would not keep it on, saying he could not stand it. It was thought at the time that the man had carcinoma of the spine. He had been admitted to the hospital, but had only remained a short time, and had not returned for treatment. After an absence of five years, the patient appears with a well-developed kyphosis, much bowed over, but in fair health and able to get about. He is satisfied with his state and will wear no brace or jacket, but the disease, which is undoubtedly tuberculosis of the spine, is still progressing. He has a rupture and also a small sinus connected with the sternum which came soon after the spinal symptoms. It is a case of tuberculosis of the lower dorsal and lumbar spine, with unusually severe and long-continued pains, and is shown as being of interest in connection with the early diagnosis.

Dr. Homer Gibney said that comparatively few cases of such late development of Pott's disease were seen. He thought the man needed support around the abdominal and upper thoracic region. Cases he had seen recently were made comfortable by means of a spinal support made of flexible steel with pelvic and abdominal belt and counter shoulder straps. It would be very difficult to put an apparatus on the man on account of the disease, which was active, as evidenced by the sinuses leading up to the ribs and sternum on the left side.

Dr. Sayre said that Dr. Taylor had mentioned that the man objected to various kinds of support, refusing to have it applied. In such cases Dr. Sayre had found an appliance of which Dr. Schapps had spoken some years ago—a pelvic belt with two uprights in front, attached to a small plate which rested against the sternum—a prop for the front of the body. A man on crutches leaned against such a brace, much as our great grandmothers leaned against what they called a busk put in front of the corset.

Cervicodorsal Pott's Disease with the Application of a Gas-pipe Frame.—Dr. Homer Gibney presented this case. Dr. Downs had examined the case at the New York Hospital Dispensary. The child was thought to have some bulbar symptoms. Soon after birth could not use left arm and hand (probably slight birth paralysis) which rapidly improved under massage and manipulation. Kyphosis not present at this time. Upon examination of the case he found all of the neurological symptoms due to the development of the disease at the cervicodorsal junction. He thought the method of treatment would be of interest, and he would apply the apparatus, which is simply a rectangular gas-pipe frame to which the child is fastened by an abdominal apron. The angle at which one wishes to place the child is then adjusted to suit the conditions. The clothing is made to button in the back over the frame. The child and frame may be placed in a convenient chair in the sunlight by the window and the patient is soon transformed from an irritable, suffering child to at least a most comfortable position in which the deformity in many cases diminishes noticeably.

Snapping Knee.—Dr. Homer Gibney also presented this case. The patient had first applied for relief for a weak ankle resulting from an old fracture on the left side. He had also complained of some pain in the right knee. On examination the left foot was found in slight valgus and the evidences of an old fracture—a very good result. The knee, on right side, when extended forcibly, made a sharp noise, or snapped. The patient seemed rather proud of this accomplishment and said, after sitting long in one position, it gave him relief to snap his knee. This slipping of the quadriceps extensor tendon is to be considered infrequent in adults.

Dr. Taylor said he wished to say a word or two in commendation of the frame shown, which was not used as much as it should be, though far superior for certain cases to jackets, braces and plaster beds. Dr. Whitman had narrowed the frame, making it very light, so that it can be modeled over the edge of a table to the form required, and with the addition of the pads on either side of the spinous processes, it is an exceedingly efficient and useful appliance, worthy of more extended use than it has received, especially for children of two years or under, who have no hips to support a jacket or brace, and who are much better off lying down than walking about.

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Stated Meeting, held February 1, 1904.

Scleroderma.—Dr. E. K. Cullen showed this case; the patient was a girl aged fourteen years. Her first complaint had been burning of the back of the left shoulder. Two years ago she had struck her shoulder, but without bruising it, and ever since has had attacks of pain after slight blows in this region. In April, 1903, a whitish patch with a red border appeared over the left scapula and in August this became a patch of typical scleroderma. Its border was formed by a plexus of vessels. The thyroid was palpable. The patient was put on thyroid extract and the skin has been getting softer ever since; the change being noticed chiefly in the center of the lesion. The pain, however, has been getting more severe and less drawing and burning in character. Sensation and blood are both normal. The thyroid treatment has been kept up continuously since the onset with the exception of two weeks, when it was stopped on account of pain for which acetanilid and salol were given without success. The patient's health has been perfect, there have been no unfavorable symptoms and the scleroderma is now gone. The etiology of scleroderma is unknown, but it affects chiefly women and there is often neurotic history. The circumscribed form affects chiefly the skin and leaves muscular action unimpaired. The prognosis is more favorable than in the acute form. Thyroid and suprarenal extracts, together with baths and electrolysis, have been the chief means of treatment.

Dr. Osler said that this case was unusual in its favorable course. Since 1892 19 cases of scleroderma have occurred in the Johns Hopkins Hospital, only two of which were local. The diffuse form is the most appalling disease we know, but between the two forms there is a middle group much like the disease recently described by Gowers as local panatrophy. Two of the diffuse cases were arrested on thyroid treatment.

Myelogenous Leucemia.—Dr. Campbell reported this case, in which the spleen and the leucocytes returned to normal. The patient first complained of pain below the left rib and a good deal of weakness. Her blood count showed anemia with a leucocytosis of 350,000; many myelocytes being present. She was put on large doses of Fowler's solution and in three weeks the leucocytes had fallen to 4,000. The blood picture showed many normoblasts, but the presence of myelocytes and the clinical symptoms all pointed to leucemia. The condition improved remarkably under treatment, and on May 4, 1903, the spleen (which had originally reached the umbilicus), was just palpable, and the blood picture was practically normal. In October the patient's weight had increased much, her color was good, her spleen could not be felt, but there was some suggestion of arsenical neuritis. A recent blood count showed no myelocytes. There are 4 cases in the literature showing improvement under treatment, with various measures, and it is a question whether this case can be considered cured by the arsenic, but there is no doubt about her wonderful improvement. Dr. Osler said that three cases of this disease have occurred in the Johns Hopkins Hospital, in which the leucemia disappeared under treatment, but in only one of these did the spleen become inpalpable.

Loco Disease.—Dr. Marshall read a paper on the loco disease as seen in the West. The condition affects chiefly horses and shows itself as attacks like acute mania. A horse previously gentle will suddenly, without apparent cause, become quite unmanageable and do odd things. The disease is chronic, the animal emaciates and usually dies from cachexia. For sheep, cows and other animals the symptoms are less constant and show themselves in weakness, tremor and stiffness of gait. The disease was first described in Mexico and a little later in Texas and California. It occurs from Texas to Montana, and from California to Kansas. The cowboys claim that the disease is caused by a weed of the wild pea family. It occurs usually in young animals. Dr. Marshall autopsied 15 sheep affected with a severe form of this disease. In all but two of them he found intestinal parasites, and his work led him to believe that these parasites may have something to do with the cause of the disease, particularly as the condition shows a seasonal variation very similar to that observed in other parasitic diseases. The loco disease is therefore probably not due at all to eating the loco weed, but is a name under which many diseases are included, some, if not all, of them, probably parasitic. The ranchers experience great loss from this condition, and the question as to the nature of the disease is an important economical problem.

Pneumonia in Diabetes.—Dr. Futcher reviewed this subject, it being suggested by a recent case in which, with the usual symptoms of diabetes, there was an acute and fatal pneumonia with all the physical signs, but without cough, expectoration or chill. Out of 134 cases of diabetes at the Johns Hopkins Hospital three have had lobar pneumonia—all fatal. The disease is, therefore, comparatively rare, but it is very acute and fatal and often insidious. Dr. Smith reported a case of diabetes with coma in which pneumonia developed, and though the case was regarded as hopeless, the patient got perfectly well.

BOOK REVIEWS.

AMERICAN TEXT-BOOK OF SURGERY. Edited by Drs. W. W. KEEN and J. W. WIGHT. Fourth edition, 8vo, 1363 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

THIS is the fourth edition of this work and we are told that at least 40,000 copies have been disposed of. We can readily account for this popularity, as the work comprises so many features of practical value. We can only add to our previous encomiums of this work that the present edition has been brought thoroughly up to date by the addition of much new matter particularly bearing on surgery of the nervous system, the spinal cord, on surgical bacteriology, tumors, and orthopedic work.

Six new chapters appear in this edition. Military Surgery is contributed by Surgeon-General Riley, Naval Surgery by Surgeon-General Rixey. Dr. Chas. F. Kieffer contributes a chapter on Tropical Surgery; Drs. Cabot and Stone write chapters on Examination of Blood in Surgery, and Immunity respectively.

The work is thoroughly comprehensive and interesting, beautifully illustrated and from all points of view is a model volume.

TEXT-BOOK OF DISEASES OF THE EYE FOR STUDENTS AND PRACTITIONERS OF MEDICINE. By HOWARD F. HANSELL, A.M., M.D., and WILLIAM M. SWEET, M.D., with chapters by Christian R. Holmes, M.D., Casey A. Wood, M.D., D.C.L., and Wendell Reber, M.D. P. Blakiston's Son & Co., Philadelphia.

THIS book is admirable in many respects, and may be recommended as a useful source of information for students and those beginning the practice of ophthalmology, and for general practitioners who have not the time to consult the larger treatises; it is distinctly a happy medium.

The authors have devoted less space than is usual to refraction and to the rarer external diseases and conditions in general which are not amenable to treatment, and the practical utility of the book is thereby enhanced.

The authors acknowledge their indebtedness to other standard works on the eye, and realizing that no one can be best in all subjects, they have shared their task with others. The chapters on diseases of the lacrimal apparatus and the ocular symptoms in general diseases, especially prove the wisdom of this subdivision. The book is well indexed, and the publishers' work is admirable, the illustrations being far superior to those generally seen. The only exception that may be taken to this statement is that the binding offers a very small promise of durability.

Wathen's Epitome of Histology. A Manual for Students and Physicians. By John R. Wathen, A.M., M.D., Professor of Surgery, etc., formerly Professor of Histology and Pathology, Kentucky School of Medicine, Louisville, Ky. 12mo, 220 pages, 114 illustrations. Lea Brothers & Co., Philadelphia and New York.

The author of this little volume has given us something new in the way of compends, in that he has departed from the catechetical method and has made his book a readable one—an uncommon quality, as quiz compends go. The treatment of the subject is approached both from the embryological and pathological side, thereby adding to its comprehensiveness and interest. There is a logical arrangement of short chapters, with questions at the end of each, printed in large, clear type, with a judicious use of black letter headings and italics. When possible, cuts of gross specimens show where the microscopical sections come from, and the book lies open flat upon the knee or table—two very noteworthy points. The section on bone development, the students' bugbear, is especially clear; and the homologies of male and female genitals are shown at a glance. One might wish that the fiber tracts in brain and cord were more fully described, and that the Graafian follicles were traced in their development; but aside from these the book is one of which any author might well feel proud. The student who reads this manual carefully and thoughtfully need have no fear of a conditional examination in histology.

The Story of New Zealand. A History of New Zealand from the Earliest Times to the Present, with Special Reference to the Political, Industrial and Social Development of the Island's Commonwealth, including Industrial Evolution dating from 1870, the Political Revolution of 1890, the Cause and Consequences, and the General Movement of Events Throughout the Four Periods of New Zealand History. By Professor Frank Parsons, Ph.D., of the American Academy of Political and Social Science; Director Department of History in the Bureau of Economic Research, Washington, D. C., etc.

This is one of the volumes of the Equity Series edited and published by Dr. C. F. Taylor, the editor of the *Medical World* of Philadelphia. Among other volumes of the series are "The City for the People," "Direct Legislation," "The Telegraph Monopoly," "Rational Money and the Bondage of Cities," all by Professor Parsons, and "The Organization and Control of Industrial Corporations," by Frank Horack. All of them contain valuable information on subjects that are of present-day political interest. This present volume is a résumé of what has been done in New Zealand by legislation in order to make life more livable for all classes.

There are many chapters in it of special interest to medical men. Those on the Factory Laws, on Old Age Pensions, on the Labor Problem, and Certain Phases of Labor Legislation contain an immense amount of suggestive material which is not merely theory, but is the result of actual experimental observation in New Zealand.

Most people know that New Zealand has attempted to accomplish by means of legislation many reforms that are usually considered ideal rather than practical. Somewhat like the use of small animals in the laboratory for experimental demonstrations, it seems to be not inappropriate that little New Zealand should thus have offered herself as an example of how certain supposedly Utopian theories work out in practice. It must be said that many of the experiments have given successful results where this might not have been expected. The whole character of the legislative movement in New Zealand, however, will have to work itself out further before the decision can be read. Meantime Professor Parsons' book gives an excellent idea of what has been attempted with perhaps a little too favorable recognition of the results, for as yet time is needed properly to appreciate what the ultimate consequences of the movement in New Zealand will be.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

The Story of New Zealand. By Dr. Frank Parsons. 8vo, 840 pages. Illustrated. C. F. Taylor, Philadelphia.

Diseases of the Eye. By Dr. L. Webster Fox. 8vo, 584 pages. Illustrated. D. Appleton & Co., New York and London

Social Diseases and Marriage. By Dr. Prince A. Morrow. 8vo, 390 pages. Lea Brothers & Co., New York and Philadelphia.

Transactions of the American Gynecological Society. Volume 28. 8vo, 343 pages. Illustrated. W. J. Dornan, Philadelphia.

Bacteriology of Milk. By Drs. H. Swithinbank and Geo. Newman. 8vo, 605 pages. Illustrated. E. P. Dutton & Co., New York.

Transactions of the National Association of United States Pension Examining Surgeons. Vol. 1. 8vo, 215 pages. Rochester, N. Y.

Treatment of Neurasthenia. By Drs. A. Proust and G. Ballet. Translated by Dr. P. C. Smith. 12mo, 213 pages. E. R. Pelton Co., New York.

The Lymphatics. By Drs. G. Delemare, Poirier and B. Cuneo. Translated by Dr. Cecil H. Leaf. 301 pages. Illustrated. W. T. Keener & Co., Chicago.

A Manual of Operative Surgery. By Sir Frederick Treves. Volume 2. 8vo, 822 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

Mammalian Anatomy, with Especial Reference to the Cat. By Dr. A. Davison. 8vo, 250 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Special Report on Diseases of the Horse. United States Department of Agriculture Reports. Revised edition. Government Printing Office, Washington, D. C.

The Four Epochs in a Woman's Life. By Dr. A. L. Galbraith. Second edition. 8vo, 244 pages. W. B. Saunders & Co., New York, Philadelphia and London.

ORIGINAL ARTICLES.

THE PATHOLOGICAL ANATOMY OF SHIGA BACILLUS INFECTION OF THE INTESTINES IN INFANTS.

BY JOHN HOWLAND, M.D.,

OF NEW YORK;

PATHOLOGIST TO THE NEW YORK FOUNDLING HOSPITAL; ASSISTANT ATTENDING PHYSICIAN, ST. VINCENT'S HOSPITAL.

THE bacillus of dysentery (Shiga) first proved by Shiga[1] to be the cause of the epidemic dysentery of Japan, has been shown by the work of Flexner, Kruse, Müller, Drycke and others to stand in direct causal relation to the dysenteries epidemic, endemic and sporadic of the tropical and temperate zones, and its etiological importance is now universally recognized.

The pathological lesions in adults induced by infection with this bacillus were briefly stated by Shiga[2] to be more superficial than those caused by the *Amœba coli*, and he noticed that while the mesenteric glands were regularly enlarged the spleen, unless some complication was present, was unaffected.

Flexner[3] reports briefly the autopsies of three cases in Manila, the lesions consisting in swelling, congestion, and hemorrhage into the mucous membrane with slight exudation on to the surface in one case and very small ulcerations in another. He states that histologically "the changes appear in the mucous membrane, submucosa and muscularis, being most marked in the former situations. Those of the mucous membrane consist of coagulative necrosis with exudation of fibrin and polymorphonuclear cells. . . . The pseudomembrane is a close-meshed network of fibrin enclosing multinuclear, often fragmented cells. . . . The submucosa is always much altered. . . . Here are found hemorrhages of variable size, while in the interstices of the tissue, some fibrin appears. More marked, however, are cellular accumulations which are present, not uniformly, but in irregular areas. . . . The character of the cellular exudate is quite uniform. Excluding the red blood cells the new cells consist chiefly of plasma cells. . . . In the submucosa, infiltration, hemorrhage and fibrin formation take place also beneath an intact or almost intact mucous membrane. . . . The muscular coat shows only hemorrhages. . . . The peritoneal tunic is usually unaltered."

He emphasizes the fact that the polymorphonuclear leucocytes play a very insignificant rôle in the process of infiltration of the submucosa, whereas in the affected mucous membrane they are much in evidence. The bacteria were abundant in the fibrinous exudation on the mucous membrane and in the necrotic tissue; he could not find them in the unaffected tissue and believed the changes in the submucosa to be toxic in origin.

Strong and Musgrave[4] give a summary of the changes observed in many autopsies performed by them in Manila. They found the changes mostly in the large intestine but extending usually for a variable distance into the ileum. The whole wall of the intestine was thickened. The superficial part of the mucosa was necrotic and usually hemorrhages were found beneath this. The solitary follicles were swollen and red. In the very acute cases no definite ulceration was observed but only a general superficial necrosis of the mucosa. Microscopically there was necrosis of the mucous membrane with distension of the blood vessels and extravasation of blood. An extensive cellular infiltration of the mucosa was the rule and there were hemorrhages into the submucosa and edema of the same. Plasma cells were increased especially around the blood vessels. Edema was found even in the muscular coats. The mesenteric glands were uniformly much enlarged. Bacilli of typhoid colon form and staining properties were found in the mucosa, and cocci often mixed with them and though the latter were only superficially situated the bacilli were found sometimes not only in the mucosa but all through the areolar tissue, the muscularis mucosæ and submucosa down to the muscular coats. In the other organs were no constant changes. No mention is made of fibrin.

Duval and Bassett[5] in a preliminary paper first pointed out the relationship between the *Bacillus dysenteriæ* (Shiga) and the summer diarrheas of infants. They reported 42 positive cases.

Wollstein[6] reports the finding of the bacilli in 39 cases of infantile diarrhea occurring during the winter months out of 114 studied, but many of the negative cases were normal children and in all cases having blood and mucus in the stools the bacilli were present.

Numerous other cases in addition have been reported and the *Bacillus dysenteriæ* (Shiga) is now generally accepted as the cause of the majority of the various forms of diarrhea in children.

The apparent discrepancies in the different types of cultures obtained from various sources have partly disappeared in the light of the observations of Martini[7] and Lenz[8] who showed by reactions and cultural characteristics that there are at least two types of this organism known to us as the true Shiga (not fermenting mannite) and the Harris or Flexner-Manila (fermenting mannite). The latter of these is the type chiefly found connected with infantile diarrhea in New York, according to Wollstein, only one of her positive cases being of the true Shiga type.

Gay and Duval[9] have recently reported three cases in adults in which both types of the organism were found, in one case the acid or Harris type predominating, in another the alkaline or true Shiga type predominating and in a third the number of positive tubes being approximately the same. No cases of double infection in infants have as yet been reported. (This statement was true at the time that this was written but since then at least six cases of double infection in infants have been found.)

The autopsies whose findings I wish to report took place at the New York Foundling Hospital, the Babies' Hospital and the Nursery and Child's Hospital. The organism was proved to be present in the great majority of cases by an examination of the stools but in seven cases it was obtained post mortem by scraping the mucous membrane of the colon and in three cases it was obtained both ante mortem and post mortem.

The organisms found in all these cases corresponded in all particulars to the type known as the "acid" or "Harris" or "Flexner-Manila" organism, that is, it did not ferment glucose, saccharose or lactose but did split mannite with acid formation. It produced an early acidity in milk with a subsequent alkalinity and agglutinated with the "Harris" serum in high dilutions.

The autopsies were obtained as soon as possible after death the pieces of the organs placed in equal parts of 95 per cent. alcohol and 10 per cent. formalin. After from one to three days they were transferred to alcohol and mounted and cut in paraffin. The staining was done with hæmalaun and eosin, sections for bacteria were stained by the Gram-Weigert method and for those negative to Gram with borax-blue and differentiated with one-half per cent. acetic acid. The Weigert stain for fibrin was used to demonstrate fibrin.

The first 17 cases were winter cases occurring between November 1 and April 15, and the last 15 summer cases between May 1 and September 1. There seems to be no difference in the histological findings due to the time of year. From a study of these cases it seems that they fall with considerable accuracy into several different groups, according to the histological findings and with the description of each group I report a typical case.

Group A comprises five cases and represents the most severe changes met with which are more like those found by Flexner and Strong in the adult dysenteries of Manila than any I have to report. The following is a well-marked case:

Case I.—T. W., five months old; was admitted to hospital suffering from intestinal indigestion. During the first month he improved very much and gained some weight, then got up diarrhea and began to lose weight. A day or two afterward, the first trace of blood appeared in the stools, only small in amount, but coincident with this, a rise in temperature from 99° to 103° F., and it remained high, sometimes up to 104° F., till his death eight days later. Stools toward the last showed no blood whatever, but were yellowish-green with some mucus. Toward the end there was considerable abdominal rigidity and tympanites. The *Bacillus dysenteriæ* was obtained by culture from scrapings of the intestinal mucosa.

Autopsy.—Liver greatly congested with fatty infiltration; kidneys congested and degenerated; spleen congested; hypostatic pneumonia in both lungs; peritoneal cavity contained cloudy serum. Between the loops of intestine there are some delicate bits of fibrin. There is no marked injection of the vessels and the peritoneum has lost only in part its normal shining appearance. Stomach normal. Small intestine appears normal except for slight swelling of Peyer's patches and solitary follicles. Large intestine shows extensive changes, more marked at the lower end. The wall of the sigmoid and rectum is very much thickened. In the cecum the mucous membrane has lost its normal smooth appearance interspersed with granular areas and marked congestion. In the sigmoid and rectum the mucous membrane is covered with a grayish pseudomembrane that strips off with difficulty, taking with it all structures down to the very much thickened submucosa. Mesenteric glands moderately swollen and congested.

Microscopical. The surface epithelium of the small intestine is partially denuded. The mucous membrane excepting Peyer's patches is apparently normal. Peyer's patches are moderately swollen; there being a moderate hyperplasia of the lymphoid cells only. No necrosis of cells. Submucosa and muscularis normal. Sections of the large intestine show a diffuse necrosis of the mucosa varying in intensity, in some places only the superficial edge is necrotic in other places the necrosis extends through the entire depth and as far as the muscularis mucosæ. All the parts of the mucosa are affected though the Lieberkühnian glands suffer especially. The blood vessels are either injected or closed by means of pink thrombi. These thrombi show little or no fibrin and would appear to be made up of coalesced red blood corpuscles. The surface is not covered with a definite membrane, the necrotic tissue adheres to the subjacent living tissues in general, occasionally it is lifted up and gives the impression of being a pseudomembrane. At the line of junction of the living and dead tissue there is an invasion of the latter by polymorphonuclear cells and there is a general increase of the cells in the mucosa. Nuclear fragmentation is not abundant. The solitary follicles show a somewhat more marked hyperplasia than in the small intestine, the centers showing endothelial proliferation. The mucosa is deficient over the follicles. The submucosa is edematous and contains a greatly increased number of mononuclear cells with eccentric nuclei some of which are plasma cells. The muscular coat except for the fibrous septa which show an increased number of mononuclear cells is normal. There is a massive bacterial development in the necrotic mucosa

and extension of bacteria a certain distance into the adjacent living mucosa. The bacteria consist of forms staining with Gram and decolorizing by Gram; among these are cocci and innumerable bacilli. The invading organisms also consist of cocci and bacilli among which are forms having the colon-typhoid morphology. Cultures from this case gave colon bacilli from the peritoneum and all the organs while, in addition, the *Bacillus dysenteriæ* was obtained from the intestinal contents.

In these cases the change is a pseudomembranous one though the membrane is by no means continuous but of irregular distribution; in two cases however, it is very extensive. This pseudomembrane is composed chiefly of necrotic tissue, desquamated cells and countless bacteria. Fibrin plays in it a very small part, two of the cases and those the most intense showing none at all. There is necrosis of the mucosa in all these cases and it is this which chiefly gives the appearance of a false membrane but the necrosis does not extend beyond this coat. In this necrotic tissue and at its border there are hemorrhages and thromboses and it is divided from the healthy tissue by a zone of mono- and polynuclear cell infiltration.

The submucosa in four of the cases of this group is much affected, it is swollen both from edema and from cellular infiltration. This infiltration is composed of mononuclear cells many with the eccentric nuclei characteristic of Unna's plasma cells and is found most marked about the blood vessels. The submucosa in the fifth case is unaffected. The muscular coat is spared except for a slight mononuclear cell infiltration along the fibrous septa in one case and the peritoneal coat is normal save in the case of peritonitis.

It is interesting to note in this connection that though such cases in adults run as a rule very acute courses one of these children lived eighteen and two, twenty-one days after the bacillus was isolated from the stools while the other cases survived only six and eight days after the stools contained mucus or blood.

Two cases were so called "terminal infections" occurring in nephritis and measles respectively, the latter being also complicated by an intercurrent diphtheria.

In Group B, comprising four cases, we find a different picture. Here the mucous membrane in both small and large intestines is in general in a good state of preservation, it is the lymphoid elements that suffer. The following is a characteristic case:

Case II.—B. F., age nine months, twenty-seven days, brought to the hospital in bad condition with diarrhea and without any accurate previous history. Was very emaciated, had meningeal symptoms, stiff neck, irregular pupils and internal strabismus. Stools most of the time were yellow occasionally green with a trace of blood, two to five a day. Temperature at first below 100° F., rising irregularly till death at 104°. The bacillus of dysentery was isolated three days before death. Length of illness in hospital, fourteen days.

Autopsy.—A very much emaciated child; lungs edematous; liver very fatty; stomach normal; upper part of small intestine normal. In the lower two feet the Peyer's patches are enlarged with small superficial ulcerations over them and the mucous membrane appears a little thickened. In the large intestines there is congestion most marked in the neighborhood of the ileocecal valve. The solitary follicles are dimpled. The changes are slight in the descending colon and sigmoid. The mesenteric glands are slightly enlarged.

Microscopical. Small intestine. General mucosa shows little alteration. As the confines of the swollen lymphoid nodules are approached the villi are swollen and rendered more obtuse by an increase of the lymphoid cells. The lymphoid masses are markedly enlarged, the new cells being of the lymphoid habitus. From the center of the mass there is a funnel-shaped depression in which the lymphoid cells often stain poorly and over which the mucosa is imperfect. The submucosa and muscle show no striking alteration. A. Colon: The mucous membrane of the large intestine shows in general no striking change but the solitary nodules are enlarged in a manner similar to that described in the small intestine and over them the epithelial layer is deficient. Bacteria of any form or staining properties are few in number.

In three cases, both small and large intestines were involved in the process, in the fourth only the colon. The change consists in a hyperplasia of the lymph follicles both agminated and solitary, and this hyperplasia is lymphoid in three of the cases and endothelioid in the fourth. The elements of these follicles show a tendency to invade the surrounding tissue. Over these follicles there is a deficiency of the epithelium and more or less excavation of the follicles themselves, causing the well known "dimpling." The submucosa was in all cases approximately normal nor did the muscular or peritoneal coats show any change.

The Case of Park and Carey,[10] the only autopsy in an infant suffering from undoubted Shiga infection that I have been able to find reported up to this time, evidently belongs to this group the lesions being chiefly in the solitary follicles. Of this group three of the cases were known to have been ill for fourteen days or over and the fourth had diarrhea for only five days but before this his stools were green and rather numerous and had not been examined so that it is possible that the bacillus was present for a longer time. These changes are what one would expect in subacute cases with a more delayed termination and as mentioned above this is true of three of the cases at least and possibly of the fourth.

Group C includes those cases characterized by superficial necrosis and ulceration in the mucous membrane not limited to the follicles as in Group B, and not accompanied by the formation of a pseudomembrane as in Group A. Of this group

there are five examples. One of these is as follows:

Case III.—J. S., seven months twenty-four days; a well-nourished child began to be ill acutely with temperature 103°F. rising in twenty-four hours to 104.5° F. Stools at first brown and loose two to four a day. The temperature then dropped to normal and after three days stools were normal for twenty-four hours. Following this a rise of temperature to 103° F. and stools became frequent and green with mucus and blood. Death five days later despite the injection of 10 c.c. of "Harris" and 10 c.c. of "Seward" serum. Temperature for the last three days 100° to 102° F. The Shiga organism was isolated from the stools five days before death and was also found post mortem from the scrapings of the mucous membrane of the colon.

Autopsy.—Slight congestion in the lower lobes of lungs; liver fatty; spleen small and firm; stomach normal; lower six inches of small intestine were slightly congested; the large intestine was congested and in places there were small hemorrhages into the mucosa. The mucous membrane, especially near the ileocecal valve presented very small superficial yellowish areas of apparent necrosis.

Microscopically, the small intestine was practically normal; the large intestine, throughout its whole extent presented congestion, in the sections from the neighborhood of the ileocecal valve the blood vessels of the mucosa and submucosa were enormously dilated, in the former situation there were actual hemorrhages. There were small areas near the hemorrhages whose cells stained poorly and there was actual, although superficial, loss of substance. There was considerable inflammatory reaction around these areas. The submucosa was much infiltrated with mononuclear cells, especially in the superficial portion. The muscularis was normal. In other parts of the colon the pathological changes were less marked.

Bacteria: Cocci and bacilli positive and negative to Gram were found in great numbers in the neighborhood of the necrotic portions. No especial type seemed to predominate.

The changes in these cases consist in congestion and hemorrhage into the mucosa with necrosis of isolated portions of the mucous membrane which necrotic portion may be exfoliated so as to form ulcerations on the surface. The necrotic area and ulcerations are usually surrounded by a zone of inflammatory reaction. The lymphatic tissue shows more or less participation in the process. The submucosa escapes with the exception of one case where it shows a cellular infiltration. The other coats are unaffected.

Two of these cases were very acute, lasting but two and eight days respectively while the others ran a course of about two weeks.

The Group D, embracing those cases that show microscopically but few discoverable lesions, is a large one, numbering 14 cases. The following is a typical case:

Case IV.—J. W., two months old; admitted to hospital March 25 with pneumonia. Died April 3. He had one to three yellow and green stools a day, no mucus and no blood. Temperature before death for two days 98°-100° F. Five days before death no Shiga bacilli; two days before death the bacilli were isolated.

Autopsy.—Lungs typical and very marked bronchopneumonia; spleen was large, dark-red and soft; liver and kidneys were degenerated; stomach normal. Small intestine.—There were congested Peyer's patches and the solitary follicles were pigmented and presented typical "shaven-beard" appearance most marked low down. The large intestine was slightly congested and the follicles prominent.

Microscopically: Ileum.—The solitary follicles and Peyer's patches were a little enlarged from an increase of the lymphoid cells; except for this, the appearance was normal. Large intestine: The mucous membrane was in an excellent condition of preservation. The follicles were slightly swollen, but no other changes. Bacteria.—These are very few and very superficial. Spleen is much congested with hyperplasia of the pulp.

Several facts may contribute to account for the paucity of the pathological findings. I have not considered the loss of the superficial epithelium as a pathological lesion and have only regarded loss of substance as true and not an artifact when it has been surrounded by a definite reactionary zone. The autopsies in most of the cases unfortunately could not be obtained immediately after death as they should be to draw any conclusions from the condition of the superficial epithelium and loss of substance occurs so easily that in order not to arrive at any false conclusions this plan was adopted. It is possible that autopsies obtained a few minutes after death will allow of some deductions in regard to the epithelial coating.

Then, too, the microscope fails to help us very much in the vascular changes in the mucosa on account of the various procedures to which the tissue has to be subjected in the course of hardening and for this reason the macroscopic examination probably gives us a truer conception of the amount of congestion.

And lastly five cases of this group were terminal infections occurring in children suffering from serious and even fatal diseases and others were almost entirely in badly nourished institutional infants to whose marasmus the infection with the Shiga bacillus was terminal. The infection was of a comparatively short duration and their reaction undoubtedly poor. Beyond congestion, moderate hyperplasia of the lymphoid tissue and in one case a little cellular infiltration of the superficial portion of the submucosa there was very slight histological change.

One case presents lesions quite distinct from any of the others. The ulcerations were very deep and were in the process of repair, death being due to marasmus after all intestinal symptoms had ceased and the Shiga bacillus had disappeared

from the stools, nor could it be found post mortem by scraping the mucosa.

The description of this case is as follows:

Case V.—J. R., fifteen months; had suffered for months previous from malnutrition and vomiting. Admitted at the age of ten months. Weight seven pounds and fifteen ounces. Improved slowly and one month later was taking food well and gaining in weight; then vomiting and loss of weight though the stools were normal. Three months after admission the stools became loose, four to six a day, no blood but later a little mucus and undigested food. This condition persisted for a long time and twenty-nine days after the beginning of the diarrhea the *Bacillus dysenteriæ* (Shiga) was obtained from the stools. Two days later the bacillus was no longer found and at the autopsy three weeks later it could not be recovered by scraping the mucous membrane of the colon. The child failed constantly and died in a condition of extreme marasmus weighing but six pounds four ounces.

Autopsy.—Lungs congested; liver small and dark; spleen dark red, follicles prominent; stomach and duodenum normal; Jejunum shows two small ulcers; Ileum.—Peyer's patches slightly swollen and a few small ulcers were present in them. Colon.—Here were many ulcers extending through the mucosa and even down to the muscular coat but the peritoneal surface was quite smooth everywhere. The ulcers were irregularly oval or round with raised edges and were not limited to the solitary follicles which were not enlarged.

Microscopical: In the small intestine the ulcers are relatively superficial and involve the layer of the crypts but do not extend through the mucosa. The base consists of granulation tissue diffusely spread out extending beyond the limits of the ulcer and invading the adjacent mucous membrane, the crypts of which are widely separated and also invading at a distance the submucosa. The muscular coat escapes. In the large intestine the chief lesion is an ulcerative one affecting the mucous membrane and to a marked extent the submucosa. The ulcer is clear, the base of it consisting of granulation tissue in a state of advanced formation. The superficial edges of the ulcers present a reticulated appearance due to a superficial necrosis of the granulation tissue in which fibrin and degenerated mononuclear cells are contained. Where the glands were retained many had become dilated so as to form small cysts. The spleen is interesting in showing a marked endothelial transformation of the germinal centers of the Malpighian bodies. Bacteria.—Very few cocci and bacilli found on the surface of the ulcers as well as in the mucous membrane.

Two cases could not be classed with any of the groups owing to their unsatisfactory microscopical examinations while one case is worthy of special mention, though presenting practically no abnormal change on account of the fact that it was a case that had recovered completely from the infection to fall a victim later to pneumonia.

From the foregoing it will be noticed that the severe cases are decidedly in the minority. The lesions occur with the greatest frequency in the mucosa of the colon and the lower few inches of the ileum, those in the colon being usually much more intense and extensive. The pseudomembrane in one case, however, is confined entirely to the small intestine, the ulcerations in one case were confined entirely to the small intestine, and one case, although only a little of the ileum was affected, showed its most intense process there. Though the submucosa is at times affected there is no considerable change in this unless the mucosa has suffered severely. Only in the most intense inflammations does the muscular coat show participation in the process and then very slightly while the peritoneum escapes, the case with general peritonitis being an exception.

As far as the other organs are concerned there were no characteristic findings. The mesenteric glands are usually somewhat enlarged, rarely markedly so, and grayish or pinkish. The lungs show hypostatic congestion and small areas of bronchopneumonia unless the Shiga infection is secondary to some more pronounced pulmonary lesion. The liver is fatty in about the same percentage as in other infantile conditions. The spleen is, ordinarily, unaffected but when some other infection is added presents the ordinary characteristics common in infectious diseases. The kidneys show, as a rule, cloudy swelling.

In eight cases cultures were made from all the organs at autopsy but in no case was the bacillus found except in the intestinal tract. The tubes from the organs when transplanted in small quantity, except the lungs where many different organisms were found, either remained sterile or showed a growth of colon bacilli. In one case the liver gave streptococci. This negative bacteriological finding is the characteristic one in adults though cases of a general blood infection are reported. The method advised by Flexner of plating considerable quantities of tissue by which he was able to demonstrate the presence of bacilli in the liver and mesenteric glands was not employed.

An examination for microorganisms gives no very definite results. An innumerable host of bacteria, cocci and bacilli, are present in the pseudomembrane and in the necrotic tissues; in the center of these masses they were about equally distributed, but one receives the impression that, in the tissue surrounding the bacilli of the colon-typhoid morphology and staining properties predominate, but it is of course impossible to say that these are all Shiga bacilli. In the milder grades of inflammation the organisms of any kind are few in number, very superficially situated and no particular type predominates. In this series of cases the organisms invaded the submucosa in only one case.

In an examination for bacteria in the sections, my findings agree more nearly with those of

Flexner[3] in adult cases, who found a general admixture of organisms on the surface of and in the mucosa with a submucosa uninvaded, rather than with those of Strong and Musgrave[4] who found organisms not only in the mucosa but all through the areolar tissue, muscularis mucosæ and submucosa down to the muscular coat.

It is interesting at this time to compare somewhat in detail the pathological findings in these cases with those observed by Flexner,[3] and Strong and Musgrave[4] in Manila, the specific germ being the same. When we do this we find that only one of these groups (A) is comparable in any way with their cases though this bears many striking resemblances to the Manila cases. There is a pseudomembrane composed of necrotic tissue, emigrated and desquamated cells and myriads of bacteria. Flexner lays great stress on the fibrin in this pseudomembrane, while Strong and Musgrave do not mention its presence. A moderate amount of fibrin was found in some but not in all of my cases. The submucosa is much affected according to these observers and this was my observation and the changes were the same, but Flexner speaks of much fibrin formation in this coat as well as hemorrhages, the former of which Strong and Musgrave do not mention, nor did I find fibrin or hemorrhages in this situation save in one case where hemorrhage continuous with that in the mucosa was found. Flexner also says that the submucosa may be affected with an intact or, almost intact, mucous membrane while in many cases when the submucosa participated in the process, it was only when the mucous membrane was greatly damaged. Flexner does not speak of but Strong and Musgrave mention subacute cases with hyperplasia of the solitary follicles and superficial erosions which suggests my group (B) with the follicular excavations. The other varieties which I have described find no prototypes in the published reports of Manila cases.

The foregoing report shows unmistakably that cases of Shiga bacillus infection exhibit most diverse pathological anatomy. The gross and microscopical changes of the extremes of these cases are so different that at first sight it would seem scarcely probable that they are caused by the same microorganism. There are indeed many considerations which must be taken into account before a final opinion is passed upon the question as to what extent the lesions found are to be ascribed to the action of this bacillus.

It seems to me that in discussing this point, which is among the most important of all, we can not afford to disregard the facts of clinical observation. A moment's reflection on the clinical course of the diarrheas of infants brings forcibly to our attention the common observation that some cases are extremely mild and respond almost immediately to ordinary therapeutic measures. In conformity with this fact it can be stated on the basis of my observations that a large percentage of fatal cases fails to show evidence of profound structural lesions. In view of the slight nature of these lesions the question arises as to what extent the infection is to be conceived as a cause of death in infants. As regards this question, it may be said immediately that among these cases a percentage must be looked upon as intercurrent or so-called "terminal" infections in children already debilitated by previous disease, whereas in the remainder the very fact that the children are institutional children in a very depreciated state of health must be considered. It seems, therefore, to me that these slighter grades of infection in more vigorous infants are the ones possibly which respond so promptly to remedial measures.

In considering the severe lesions, particularly the ulcerative ones, the question immediately arises as to what extent the entire process is to be regarded as due to the Shiga bacillus. We are here confronted with the identical problem that has to be considered in dealing with similar infection in adults and thus far it has not been possible to separate sharply the damage done by the Shiga bacillus and that which is subsequently done by the whole host of microorganisms pyogenic and others normally contained in the intestinal tract. This much may be said, the evidence is in favor of the belief that the primary necrotic lesion is the result of the action of the bacillus of dysentery, the subsequent ulceration being brought about not improbably by the interaction of various microorganisms and the ordinary processes of demarcating inflammation. Beyond this point it does not seem possible to distinguish the action of the various microorganisms in the intestines.

The lesions in the intestines in children as in adults must for the present be conceived to be of two kinds, first those due to the action of the dysentery bacillus as already explained and second of toxic products of this and perhaps other organisms as is shown by the lesions of the submucosa and elsewhere among which the microorganisms have not been discovered. In this regard there is a conformity in the condition found in children and in adults.

It is important to take cognizance of the fact that after all, in my cases, the lesions found were not usually typical pseudomembranous inflammations, the pseudomembrane appeared either on the surface of ulcers or as isolated areas upon the mucous surface of the gut. In this regard the changes in children seem to be in contrast to those thus far described in adults. But a still further distinction is found in the much more common involvement of the solitary and agminated lymphatic structures in children, the same structures in adults usually escaping participation in the pathological process.

If we endeavor to sum up the case as is here made out for the Shiga bacillus we shall have to say, as it seems to me, that there are comprised under the lesions associated with it all grades and types of diarrheal disease as distinguished by clinical symptoms and pathological findings and that it can be affirmed that no particular type is

distinguished from the others by a special etiological origin.

THE UTILIZATION OF THE LOWER LIP IN RHINOPLASTY. A NEW PROCEDURE.*

BY CARL BECK, M.D.,

OF NEW YORK;

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, VISITING SURGEON TO THE ST. MARK'S HOSPITAL AND THE GERMAN POLIKLINIK.

IN this patient, a woman aged fifty-five years, I tried a method of repairing a nasal defect, which, as far as my knowledge goes, has not been attempted before, viz., to utilize part of the lower lip and chin for restoring the lost tissues of the left side of the nose.

The patient suffered from epithelioma, the microscopical corroboration of the diagnosis being furnished by Dr. Henry T. Brooks. As indicated by the scars on the forehead and cheek, she had been the object of previous rhinoplastic efforts,

Fig. 1.

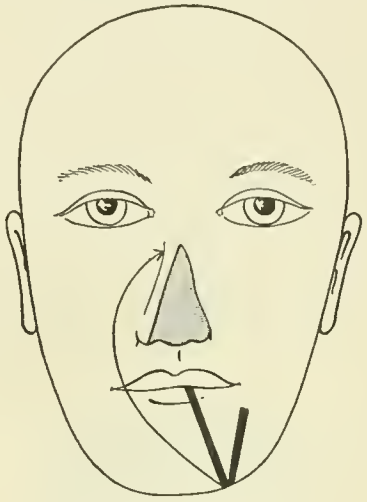
Defect caused by recurrent epithelioma.

which appeared to have been entirely successful at the time they were made, about three years ago. When I first saw the patient, now two years ago, the disease had recurred and nothing was left of the transplanted flaps. As the previous operations had left no available tissue in the immediate vicinity of the diseased area, I resorted to the Italian method, taking a large flap from the left arm. Although considerable shrinking took place, agglutination became perfect, and no loss of substance was noted.

During last summer there was another recurrence, the destruction this time being more extensive, the mucous membrane of the left nostril being completely exposed, as shown in Fig. 1.

If I had not feared to impair the agglutinating tendency of the tissues by irradiation, which creates such unfavorable conditions for subsequent plastic operations, I would have resorted

Fig. 2.



Outlining of the flap.

to Roentgen treatment. But the experience of others, as well as my own, induced me to look for another plan, the modus operandi being as follows:

After outlining a triangular flap, the lower lip was divided in its whole thickness from a little over an inch from the left angle of the mouth downwards to the chin (Fig. 2). The flap-formation was finished by dissecting upward to the angle of the mouth, stopping about one-half of an

Fig. 3.

Appearance of flap two days after operation (the black surface above the upper lip indicates the non-united wound margin of the flap).

inch below in order to obtain a suitable bridge. The tip of the triangular flap was then turned around and sewed to the margins of the nasal defect, after extensive exsection of the epitheliomatous area. The upper portion of the flap could be well approximated and fastened with silk

* Case presented to the Surgical Section of the Academy of Medicine, January 8, 1904.

sutures. A part of the flap had to be left free, as is shown by the black sphere overlying the upper lip (Fig. 3).

No drainage tube was introduced into the left nostril at that time because I feared that this would produce undue pressure upon this part of the flap, which was simply dusted with iodoform. The gap of the lower lip, caused by the exsection of the flap, was closed by directly uniting the margins through their whole thickness with stout silk-sutures.

After a week two-thirds of the flap was severed, and four days afterward the remainder of the pedicle.

As the illustration shows, there was a small gangrenous area in the integument at the tip of the flap, while the mucous membrane remained unimpaired over its whole extent.

The ala nasi consists now of the margin of the lower lip. It may be amenable to further correction as soon as the skin formation over the

Fig. 4.

Appearance three weeks after operation.

granulating spot is perfect, when I will begin the prophylactic Roentgen treatment.

The advantages of this procedure seem to me to lie especially in the possibility of supplying throughout the whole area of the defect a mucous membrane which would restore normal conditions as far as possible. The broad wound-surfaces and the fact that the flap need not be larger than the defect because no shrinkage is to be expected, are another favorable element. How far it will influence the tendency to recurrence remains to be seen; still I presume that the conditions are more favorable now than previously. Fig. 4 shows the result three weeks after the operation.

Composition of Muscles in Polyneuritis.—In a case of polyneuritis after influenza, T. Rumpf (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 1 and 2) found the fat considerably increased in the degenerated muscles. The amount of water was reduced, but if estimated for muscle freed from fat, there was a slight increase. Other chemical changes were a reduction of nitrogen, an increase of chloride of sodium and a diminution of potassium and sodium. An analysis of the fat disclosed fatty acids which are not usually found in the human body but which occur normally in butter.

A SIMPLE AND INEXPENSIVE RHEOSTAT TO USE WITH THE ELECTRIC LIGHT CURRENT.

BY DAVID T. MARSHALL, M.D.,
OF NEW YORK.

A simple and inexpensive contrivance to enable one to use the ordinary 110-volt direct electric light current for therapeutic purposes may be made as follows:

A board about 2x1 foot is well painted and varnished on both sides. To this is fastened nine keyless and one key wall-receptacles. These are wired in series, *i.e.*, so that the current will pass through each one successively. The terminal wires are brought around to two binding posts. Wires running to binding posts are connected to *one side only* of each of the ten receptacles.

When the electric light current is connected by means of a flexible lamp-cord to the two terminals of the series of receptacles, a 16-candle power 110-volt lamp having been screwed into each receptacle, a current of a much reduced volume over what would flow through a single lamp will traverse the circuit, but it will still have a pressure of 110 volts. This of course is too high a pressure for one to endure long, if good sponge contacts are secured.

By connecting the sponges to the binding posts wired to the receptacles a current of voltages increasing by steps from 16 to 110 may be secured If smaller steps are desired, more lamps must be put in series. This arrangement gives a continuous direct current.

To obtain a *direct vibratory* current, a buzzer or call-bell movement must be connected in *multiple* with the circuit. If the electromagnet of the buzzer is of too low resistance to be put on a 110-volt circuit then it will be necessary to introduce sufficient resistance in series with the magnets to give them the right amount of current so that they will work without heating. This can be done by the amateur with the least danger of making mistakes by disjoining the wires where they are twisted together at the ends of the coils and inserting one or more lamps in series with the coils (Fig. 1).

The buzzer with the resistance lamps in circuit

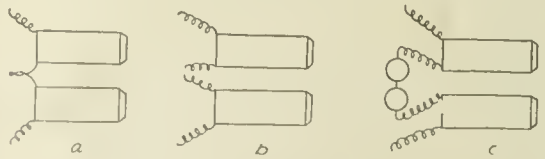


Fig. 1

is then connected in *multiple* with the lamps on the board, as shown in Fig. 3.

This arrangement gives an intermittent or vibratory direct current, the rapidity of the vibrations depending on the character of the armature, strength of spring, strength of current, adjustment of contact screw, etc. The current for the sponges is taken from the binding posts connected to the lamps 1, 2, 3, etc. These contacts

may, for convenience, be brought down to a contact switch, as in Fig. 2.

When a direct non-vibrating current is desired, all that it is necessary to do is to turn up the adjusting screw at A, Fig. 3, until the armature is too firmly pressed upon to vibrate. A better way still is to insert a wooden wedge between the armature and the magnets. This saves the trouble of adjusting the screw when it is again desired to use the vibrator.

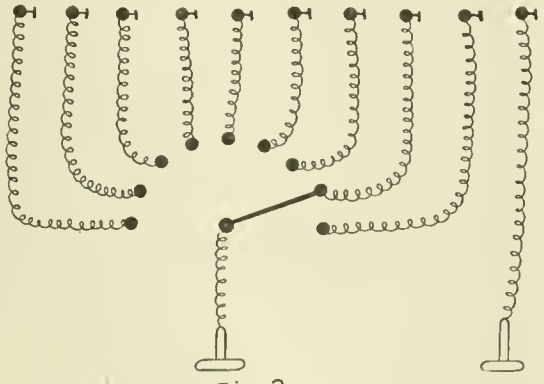

Fig. 2.

When the vibrator, with or without resistance lamps in circuit, is used, the voltage of the current traversing the lamps 1, 2, 3, etc., is reduced. Supposing the resistance of vibrator and resistance-lamp to be that of an ordinary 16-candle power 110-volt lamp, *i.e.*, about 250 ohms; then the current over lamps 1, 2, 3, etc., will have an electromotive force of about 50 volts, and the current from the binding posts 1, 2, 3, etc., will increase by steps of about 5.5 volts up to 50 volts. With twenty lamps the steps would be half as high. Variations of five volts

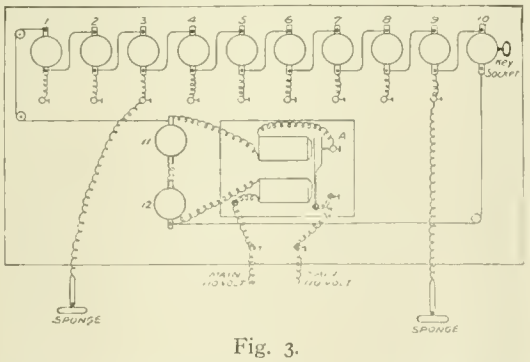

Fig. 3.

are small enough. Few people care to take continuous currents through from one hand to the other of more than 30 volts. When the current vibrates, much less than that is uncomfortable.

In this apparatus no mention is made of a milliampèremeter. A milliampèremeter may be put in circuit with the sponge wires, but for most purposes, so long as you know that you are well within the limits of safety, the sensations of the patient are a sufficient guide.

The amount of current which will traverse the sponge wires when shortcircuited between any two binding posts may be easily calculated from the formula $C = \frac{E}{R}$, the value of R being for each 16-candlepower lamp about 250 ohms.

When contacts are made on various parts of the human body the value of R may be, even with good sponge contacts, as much as 8,000 or 10,000 ohms in addition to the 250 ohms of each 16-candlepower lamp in series.

Thus if E=50 volts and R=250+8,000 (lamp +human body) C would equal $\frac{E}{R}$ =.006 ampère or 6 milliampères—an amount of current which is easily borne.

Excluding cost of labor, the cost of such an apparatus, including two yards of silk-covered lamp cord and an attachment plug, may be less than $6. Materials with retail prices in New York are given herewith:

12 16-c.p. 110-Volt Edison Base Lamps, at 14c.	$1.68
11 Porc. Ed. Base keyless receptacle, at 6c.	.66
1 ditto key, at 20c.	.20
4 No. 5½ Porc. Knobs, at ½c.	.02
10 Single Screw Binding Posts, at 6c.	.60
1 I.B. Buzzer for use on 110-Volt circuit, at $1.00.	1.00
6 feet No. 18 Office Wire, at 1c. per foot.	.06
5 feet No. 18 N.C. Silk Lamp Cord, at 8c. per yard	.40
1 Attachment Plug, at 11c.	.11
6 inches Lamp Fuse Wire	.15
1 board 1 x 2 feet	.25
2 dozen wood screws	.05
	$5.18

33 West Twelfth Street.

TRAUMATIC PYELO-PARANEPHRIC CYST.*

BY BERN B. GALLAUDET, M.D.,

OF NEW YORK;

SURGEON TO BELLEVUE HOSPITAL; DEMONSTRATOR OF ANATOMY, COLUMBIA UNIVERSITY.

The facts of the case are as follows: The patient is a male, fifteen years of age, and was always perfectly well and sound up to his twelfth year, except for an attack of scarlet fever when very young. Parents perfectly healthy. Some time during his twelfth year, while shoveling snow he was struck in the abdomen by the handle of the shovel, which necessitated confinement to bed for several days. After that time and until two weeks before admission to hospital, March 28, 1902, his health was good, except for a more or less continuous pain in the right side of abdomen.

Two weeks previous to admission, while attempting to jump on to a shed, the patient fell, his abdomen striking with considerable force on the edge of the roof of the shed. His condition required that he be carried home and put to bed, where he remained four or five days with nausea and vomiting during the first forty-eight hours, and with blood in his urine. The hematuria disappeared on the third day. After five days the patient could get around the house, but abdominal pain persisted.

* Read before the New York Surgical Society, December 23, 1903.

On date of admission, abdominal pain was intense, urine analysis was negative, general condition poor, and a small swelling was noticed in the right side of the abdomen on a level with the umbilicus. This swelling was dull on percussion; no record of further examination of this swelling, or of temperature, was obtainable.

With hot local applications, etc., the condition became better until about the middle of April, when pain became intense, accompanied by abdominal distention.

An incision was then made over and down to the swelling, followed by incision into the same, which evacuated over a quart of bloody fluid containing several large blood-clots, while partial examination of the wall of the swelling showed it to be very thick and extending inward toward the kidney. A general diagnosis of cyst was therefore clear. The edges of the sac were then sutured to the edges of the abdominal incision and a tube inserted. The bloody fluid according to pathologist's report contained "no urine."

From that time until just before I first saw the case in September, 1902, the patient's general condition improved; and the wound and cyst-cavity contracted until a regular sinus was formed. The sinus formation was complete in about six weeks after the incision, and remained stationary from then until September, in spite of local stimulating injections. During this period, urine flowed freely from the sinus; and repeated examinations were negative except for the presence of a fairly large number of leucocytes. Drainage tube had been removed permanently since the middle of July.

From about August 15 until October 1, however, there developed a series of "attacks," three or four in number, each attack consisting of high temperature (104° to 105° F.); some delirium; pain and tenderness in and around the sinus, but no swelling; and cessation of flow of urine from the sinus. Each attack lasted about two days and yielded readily to cathartics and introduction of a drainage-tube and irrigation, when the flow of urine would be resumed. On recovery, patient's general condition was a little worse each time. It was therefore decided to explore the sinus with the idea of removing the cyst wall. The operation was performed October 3, 1902.

A word more as to the urine. During an "attack," as just stated, no urine came through the sinus (suppression ?), but the urine from the bladder was uninfluenced thereby, both in quality and quantity, the latter having become almost as much as if both kidneys were normal. The amount of urine from the sinus was, between "attacks," a little less than normal each day. This precluded any necessity for finding out the condition of the other kidney should nephrectomy of the kidney on the side of the sinus be decided upon.

The operation proved to be difficult and tedious. A careful dissection (1) showed that the sinus ran into a large cavity; and (2) isolated enough of the cyst-wall of the latter for an accurate diagnosis of the actual conditions, accompanied as it was by a wide opening up of the orifice of the sinus.

The conditions found are indicated in the title. Thus: the cyst-wall, thick and dense connective-tissue, was closely adherent to the surrounding paranephric tissue, beginning right at the orifice of the sinus, the partial isolating just referred to being followed constantly by profuse venous hemorrhage. Tracing this wall in toward the kidney, the inner surface was also exposed and found to be covered by flabby granulations. These were scraped off and then it was plain by looking into the cavity that the cyst-wall extended to and into the renal sinus. In other words, there was direct continuity of tissue between the paranephric-tissue part of the cyst-wall and the renal-pelvic portion thereof. Therefore, there was a tear in the wall of the pelvis, and with each edge of the tear was connected a corresponding part of the paranephric cyst-wall. There was also considerable dilatation of the pelvis as a whole.

Hence, the cyst wall was partly pelvic and partly thick, condensed paranephric tissue, thus justifying the title, *pyelo-paranephric cyst.*

Further confirmation was obtained by observing and probing two infundibula whose orifices opened proximally into the cyst cavity; and also by finding the opening of the ureter from within the cyst. A probe was passed into the ureter, but could go readily no further than two or three inches, owing to thick granulation-tissue within the lumen of the tube. Although tough, the cyst-wall was fairly elastic and, excluding suppression, was probably stretched by accumulation of urine during the "attacks" previously mentioned. There were also found a few ridges running in all directions around the inner surface of the cyst-wall, which might have caused the obstruction to the out-flow of urine also mentioned as one of the phenomena of the "attacks." At all events, no other cause for this obstruction could be found.

These conditions, although serious, did not seem in themselves bad enough to account for the high temperature and delirium occurring in the "attacks," because the thickness of the cyst-wall was apparently sufficient to prevent any absorption of toxins or bacteria. This being so, one naturally would think of the kidney as causing these symptoms as the site either of a nephritis with bacteria and bacterial toxins, or of a condition in which toxins (non-bacterial) were being elaborated by faulty metabolism of the kidney-cells, the general condition then being an auto-intoxication rather than a septicemia or toxemia as it would be if the local condition were nephritis.

The kidney was therefore partially exposed; and one or two small but deep incisions into it were followed only by blood. As no pus was found in the cavity of the cyst, this showed the probability of the nephritis being in the form of small foci of pus; since it seemed that the nephritis must be suppurative because of the severity of the general symptoms. The kidney

could be palpated and was soft and large. Realizing that if small foci of pus were present, the other kidney might also be similarly affected, it was nevertheless felt that nephrectomy should be done, because of the progressive impairment of the patient's general health, and because the other kidney had shown absolutely no signs of any trouble at all.

Nephrectomy was accordingly performed. Many adhesions were found and much hemorrhage occurred. An attempt was made to take out the entire cyst-wall with the kidney, but was abandoned owing to adhesions and loss of blood. Therefore, the kidney being now free, was removed, together with its adrenal body, the cyst-wall being cut right across at about its connection with the pelvic wall. Some two inches or so of the ureter below and outside of the cyst-wall were exposed and removed. There was now left in the wound only a good bit of the adherent original cyst-wall. The piece of ureter removed showed granulation tissue throughout; and the kidney, on being split, showed multiple pus foci but almost of microscopic size. The pathologist confirmed the diagnosis and also excluded tuberculosis both renal and ureteral. Any share in the cyst-formation on the part of the kidney or "adrenal," was also positively excluded. Most of the wound was sutured, a drain of gauze being inserted where cyst-wall was left.

Uneventful recovery except for wound. Thus: Some six or eight weeks after operation the patient was in perfect health and had gained ten or twelve pounds. Locally, however, the wound had become a sinus with the usual small amount of seropurulent discharge. It showed no signs of healing in spite of the usual stimulating injections. A week later a piece of silk ligature came away. Still no advance for another week. Ether was then given, the sinus laid open freely, and, as suspected, the remains of the cyst-wall was found just as large and tough as at the end of the first operation. Although hemorrhage was profuse, there was no reason (the patient being in good condition) for stopping the operation and leaving any of this cyst-wall behind; so it was all dissected off and the wound partially sutured and partially packed with gauze. The patient was out of bed in three days, and the wound solidly healed at the end of two or three weeks.

Of course the interesting, and probably unusual, aspect of this cyst is not that its wall was "paranephric"—paranephric cysts being fairly common—but that the paranephric part was so closely connected with the renal pelvis that there was not only a cavity in common, but also a continuous cyst-wall, first of paranephric tissue and then of the pelvic wall. Just how unusual this condition may be I have been unable to find out; but that it is certainly uncommon may be inferred from as much of the literature as I have been able to look up (see bibliography at end of article). The cause of the cyst, judging from the history and findings, was undoubtedly traumatism. The research into the literature—for most of which I wish to express my thanks to Dr. J. F. McCarthy, of this city, while not exhaustive, was thorough, and resulted in finding mention of many pathologic cysts, renal or paranephric; of a few similar traumatic cysts; but no mention at all of pyelo-paranephric cysts, either of pathological or traumatic origin.

An attempt will now be made to assign the cyst to its proper place among cysts in general and cysts of the "kidney region." Hence, a short review is necessary of *cysts in general* and "renal cysts" (the last expression being used generically to express all cysts in the "kidney region," that is, cysts of the kidney, of the adrenal body, of the pelvis of the kidney and of the paranephric tissue).

Beginning with *cysts in general,* there are three main classes: [*A*] Truly neoplastic cysts, that is, cysts which are really neoplasms, often called *cystomata;* [*B*] parasitic cysts; and [*C*] cysts which are neither neoplastic nor parasitic. Cysts in the "kidney region" have, of course, the same classification.

[*A*] *Cystomata* or neoplastic cysts: These are being considered more and more in connection with true solid neoplasms with which they have far more in common both structurally and in etiology, than they have with "cysts." The structure of their walls, including that of the lining, is often quite complicated, so much so that the wall alone of a cystoma is almost, if not quite, identical with the structure of a solid neoplasm, thus differing entirely from the simple fibrous membrane of ordinary cysts or of the cyst which is the subject of this paper; while the contents is usually found to be made up of cell-elements mixed in with fluid or semi-solid tissue, very different from "serum" or "blood" of ordinary cysts. Many cystomata are also multilocular.

Coming to the "kidney region," the cystomata are exceedingly complicated and their origin is only in the kidney or adrenal body, or both. This origin from the cells of the Wolffian body and other embryonic structures and from inclusions of "adrenal rests," shows their complicated nature. We may therefore, safely exclude our cyst from the category of cystomata, especially of the kidney or "adrenal," if for no other reason than because no such findings resulted from the removal and examination of these structures.

[*B*] *Parasitic cysts:* This class needs only to be mentioned to be excluded from consideration. Even in the "kidney region," the kidney, "adrenal" and ureter are out of the question, as the result of the operation shows. There remains the paranephric-tissue in which there may develop parasitic cysts; but the cyst under description is certainly not of that kind.

[*C*] *Cysts which are neither neoplastic* nor *parasitic:* There are many varieties described, the chief difference between them seeming to be in many cases etiological rather than structural. The subdivisions generally accepted are: (1) Glandular retention cysts; (2) cysts in preexisting spaces other than the alveoli of glands; and

(3) cysts of new-formation or those occurring where there are no preexisting spaces.

1. Glandular retention cysts: From the nature and history of the case, these may be excluded; especially those of the kidney and "adrenal;" nor could the cyst have started as a "retention cyst" of one of the minute glands in the wall of the pelvis. There are no glandular retention cysts of the paranephric tissue, that is, primary ones.

2. Cysts in "preexisting spaces other than alveoli of glands": Among these are: Distended bursæ; ganglia (of tendon sheaths); hydrocele; and hematocele; all comprising the "transudation cysts" of some authors. There should be added: dilated lymphatics (often called simple serous cysts or hygromata); and dilated blood-vessels or "blood-cysts"; the last named not to be confounded with angioma (a neoplasm), or hematoma (a cyst of new formation); nor the serous cysts, with lymphatoma (a cyst of new formation), or lymphangiectasis (a neoplasm).

Referring to the "kidney region," and excluding "kidney" and "adrenal," there are the renal pelvis and paranephric-tissue, either of which may be the site of these cysts. Taking first the renal pelvis: The "preexisting space other than alveoli of glands" would be the cavity itself of the pelvis. A cyst developing here might grow without involving kidney or ureter; or it might remain stationary; or it might involve the kidney or ureter; or its contents might break through the pelvic wall. Comparison with the cyst under discussion shows that a portion of it, *i.e.,* the part whose wall is renal pelvis, is identical with these cysts; or, in other words, is a cyst occurring in a "preexisting space other than alveoli of glands."

Regarding, in the next place, the paranephric-tissue: Part of the cyst occurred in this tissue. If it developed in a "preexisting space other than alveoli of glands" the "space" would have to be the lumen of lymphatics or blood-vessels which are in the paranephric tissue. Against this possibility, however, are several objections: First, these "lymphatic cysts" and "blood-cysts" are rarely if ever found in a region subjected to such a severe traumatism as we know was inflicted on the patient. Secondly, these "lymphatic cysts" and "blood-cysts" are so slow in growth and possessed comparatively speaking of such a delicate wall, that communication with the cavity of the renal pelvis through its tough, fibrous wall could not be established traumatically without a traumatism so severe as to destroy the delicate cyst-wall entirely. Furthermore, this statement implies the existence of the cyst prior to the injury; of which preexistence there is absolutely no evidence. Again, the cyst-wall actually found was as tough as the renal pelvis itself.

3. Cysts of new formation; or those occurring where there are no preexisting spaces. The capsule of these cysts is usually well defined and more or less distinct from the surrounding tissue. The contents is commonly "serum"; and if of long standing, it is often impossible to tell whether this "serum" was originally lymph or blood. Among these cysts are: hematoma; lymphatoma; a "cyst-wall" of thickened tissue enclosing a foreign body; and "cysts of degeneration." The last named may be found in tendons as a variety of ganglia (distinct from that in tendon-sheaths just mentioned); or as a direct sequela to a "productive inflammation," in which case they are often multiple and small ("cystic degeneration" of some authors); they also occur in the tissue of some solid neoplasms.

In the "kidney region:" Cysts of new formation in the kidney and "adrenal" may be absolutely excluded. In the pelvic wall have been recorded small cysts occurring from traumatism and containing blood; also cysts of degeneration. These may also be excluded.

In the *paranephric tissue,* on the other hand, "cysts of new formation" are fairly common as the result of severe traumatism, and may be lymphatomata, but are usually hematomata. When we consider the structure of such cysts and compare it with that of the cyst under consideration, it would seem certain that the latter, that is the larger part of it, is a "cyst of new formation" in the paranephric tissue.

Having now placed this cyst in *two* subdivisions of cysts "which are neither neoplastic nor parasitic," a probably correct explanation of its method of formation may be had from a consideration of the etiology and method of formation of these cysts; especially since we know of the close relation of traumatism to our cyst. Thus:

In the etiology of "cysts occurring in preexisting spaces other than alveoli of glands" and of "cysts of new formation," traumatism is the most important factor, either as a predisposing cause or as a direct or exciting cause.

This statement, apparently simple, may, however, lead to misapprehension; hence the following brief elaboration: Cysts of these two subdivisions, when due to traumatism, are either recent or not. If *recent,* the contents (blood, serum or traumatic edema) is *directly caused* by the traumatism; but the capsule, as such, has not yet formed; and the "limiting wall" is simply the wall of the "space" (stretched or torn as the case may be), or the surrounding tissue (if no "space" existed). In this stage the cyst is not complete in that it has no capsule of its own.

If the cyst is *not recent,* its own capsule has had time to form, the formation consisting of a thickening of the tissue immediately around the contents, and a differentiation, more or less complete, of the same from the more remotely surrounding tissue; all this especially well marked in "cysts of new formation." This thickening, due to irritation from the presence of the contents, is regarded by some pathologists as a "productive inflammation"; but by others, as a form of degeneration, *e.g.,* a "fibrosis." Furthermore, the contents also is apt to undergo changes, especially if blood (absorption of coloring matter, deposit of fibrin, etc.). Hence the traumatism, in these complete cysts, is predisposing, the exciting cause being the fluid first produced.

Referring now to the case described and comparing with what we know of it that which has just been outlined, we may assume: (1) that the first traumatism ruptured the pelvis of the kidney and also caused a hematoma both within the pelvic cavity and in the paranephric tissue; (2) that, as time went on, the blood was gradually absorbed, and the thickened capsule (extra-pelvic portion) of connective tissue was formed (as just described) from the paranephric tissue; (3) that the opening into the pelvis, however, remained, but the capsule (extra-pelvic portion) was strong enough to hold any urine that might come through and prevent its extravasation; and (4) that the second traumatism caused a fresh hematoma, partly by tearing the inner surface of the capsule, as indicated by the ridges referred to in the history, and partly by causing small lacerations of the kidney.

Hence, as already stated, in making the individual comparisons, we may repeat (1) that the cyst, or rather cyst-wall, having two parts, the one (pelvic portion) corresponds to that of cysts occurring in "preexisting spaces other than alveoli of glands," and the other (extra-pelvic portion) corresponds to that of "cysts of new formation"; (2) that, as regards the cyst as a whole, both portions make a common capsule enclosing a common cavity; and (3) that traumatism was the predisposing cause.

BIBLIOGRAPHY.

Regeneration of Cartilage.—The question if cartilage itself possesses the power to regenerate after trauma seems to be settled by M. Matsuoka (Virchow's Archiv, Vol. 175, No. 1) who concludes that cartilage possesses no power of regeneration, for in all cases of loss of substance the cartilaginous callus took its origin from the perichondrium alone.

ERGOT IN ALCOHOLISM, MORPHINISM, AND THE GENERAL CLASS OF DRUG HABIT CASES.

BY ALFRED T. LIVINGSTON, M.D.,
OF JAMESTOWN, N. Y.

Since the publication of my first paper on ergot therapy, so many inquiries have come to me for specific directions as to the treatment of the morphine habit (the case suggesting the inquiry, being, sometimes, the doctor himself) that I have concluded that a special paper on that subject will not now be out of place.

The habitual use of other opiates, alcoholic liquors, absinthe, chloral, cocaine, etc., produces similar trains of nervous symptoms and I therefore class all these poisons together in considering the therapeutic application of ergot to the conditions produced by any one of them.

Before considering the subject proper, I wish to place myself in antagonism to a theory widely promulgated by a few and thoughtlessly accepted by many. This theory regards the habitué as the subject of a specific disease which impels him to the habituation and specific names are given the so-called diseases, such as inebriety, morphinomania, etc., dependent upon the stimulus used by the habitué. The impulse to the use of, or the craving for, the particular stimulus, is classed as a symptom of that specific disease, as cough is a symptom of bronchitis, or pain a symptom of neuralgia. A logical sequence to this theory is the irresponsibility of the subject, as it would be manifestly irrational to chide the bronchitic for coughing, or the neuralgic for having a pain. I will not now go further into this matter than to say that while I deny *in toto* the existence of such specific diseases, I do not question that diseased states of the circulation, of the nervous system and of special organs result from the improper use or abuse of these stimuli. To present my ground in another way, I distinctly prefer the old-fashioned, conventional method of hitching the horse to the cart, rather than a method which places his head where his tail ought to be.

The most striking characteristic of an habitué who leaves off, or is forcibly deprived of his stimulant, is a disturbance or agitation of the nervous system proportionate to the per diem quantity of the stimulant that had been used. I have seen this agitation so extreme that, while continuously unconscious for twenty-four hours, the patient would at a bound throw herself from the dorsal recumbent position to the prone, and even from the middle of a wide bed to the floor, before the attendant with one hand upon her could interfere. Every muscle of the body seemed simultaneously active, and the sudden and combined action inexplicable. The sensory nerves were equally alert and especially along the spine was there extreme sensitiveness.

While the cerebrospinal system was so intensely agitated, the vasomotor system seemed paralyzed, with resultant intense hyperemia and sensation of heat to the hand. It was, of course,

not possible to take the temperature with a thermometer. The two things that were soothing in this case and that resulted in twenty-four hours in restoring consciousness and calm were ergot hypodermically and galvanization of the spine.

In less extreme cases (as in this one previous to the unconscious stage), there is mental irritability and frequent importunate demands for the stimulant that had been used, and nervous restlessness. It is this agitated state of the nervous system, the sense of restlessness within, a panicky search for relief, that suggests a renewed application of the drug that had, in fact, brought about this morbid impulse, though having, in its primary action, produced a perverted sense of comfort which is again sought for; a conclusion and determination as irrational and destructive as the persistent efforts of the winged insects that, seeking the light, finally fall into the flame and are consumed. And I wish here to put myself on record as protesting most earnestly against the too common practice of many medical men of using freely and inconsiderately as to results, and absolutely unnecessarily in most instances (or, if really indicated, unnecessary dosage and unnecessary repetition of dose), all this class of narcotic stimuli. It may seem a harsh and strong statement, but I believe it to be true, that the responsibility for the vast majority of these unfortunate cases rests upon those medical men who so inconsiderately and unnecessarily make free use of these baneful drugs. I say unnecessarily advisedly, for I have demonstrated to my entire satisfaction during the past twenty-six years that sleeplessness, pain and nervousness in the large majority of instances, may be more surely relieved by ergot than by the narcotic class of drugs.

My study of this class of cases and of nervous irritability and excitability in other classes, has led me to a positive conclusion that the nervous symptoms depend directly on a disturbance of the vascular system in the nerve centers and that the circulatory disturbance is due to paralysis of the sympathetic or vasomotor centers.

The logical conclusion is therefore that the prime indication is to tone the relaxed, dilated vessels and bring about as promptly as possible an equilibrium of the circulation. There are several methods by which this result may be wholly or partly secured:

1. Cold to the head and spine by means of ice-cap and spinal bag; or hot followed immediately by cold sponging of the spine, repeating these alternately half a dozen times or more, and such séance several times a day.

2. Galvanization of the chain of sympathetic ganglia by use of the hand electrodes, stroking from occiput to sacrum, the electrodes one on either side of the spine and separated about four inches from each other. The quantity of current should be 10 or 15 milliampères and continued for twenty minutes. This should be followed by similar applications of five minutes each over the upper, middle and lower cervical sympathetic ganglia; or the static current may be used and I particularly recommend a prolonged application of the static wave, half an hour or more, to the whole length of the spine with a spark gap of five to eight inches and this séance followed by sparking over the lines of the sympathetic ganglia.

3. Dry-cupping over the entire spine and including the sides of the neck, not with the old-fashioned alcohol cups, but with the modern valve-cups which are emptied by means of an air pump.

4. Massage, which, properly applied by a skilled masseur, is certainly of much service in stimulating the general circulation and, therefore, in relieving congested areas.

5. And last, but by no means the least, effective method, hypodermic injections of ergot. While the other methods may be effective, I present this one as the most certain and the most prompt in its action. I make this assurance not only upon many practical demonstrations but upon two grounds that I think will appeal to common sense and to reason.

First, because the rationale is correct. Disturbed function, whether of nerve centers, special organs or glands, is directly dependent on altered states of the circulation in them, especially as to the caliber of the blood vessels, a hyperemic state existing, due to the relaxed and stretched muscular coat. This condition can be thoroughly corrected only by so toning and strengthening that relaxed muscular tissue that it will contract and bring the vessels to their proper caliber, thus dispersing to other parts the excess of blood they had contained. Ergot contracts the sort of muscular tissue of which the muscular coat of the blood-vessels consists, but its most pronounced action is upon those areas of such tissues as are weak, relaxed and stretched, and, therefore, upon the dilated blood vessels. When the dilated vessels in any part have contracted, the disturbance of function which they had produced in that part ceases.

I have been charged with using ergot empirically. If the statements of this, or any other paper I have written upon ergot, smack of empiricism, I would be glad to have the fact pointed out.

Second, because the method of applying the remedy places it the most surely, wholly and promptly where alone it can act. I am so often asked if ergot may not be given per orem or per rectum for the purposes for which I recommend it. Of course it may; but there is only one way by which you may be sure that it will all get where it may act for your purpose, and that is by putting it directly into the circulation. The objections which have previously existed to the general use of ergot hypodermically have been practically removed during the past six months by the special efforts of a few pharmaceutical houses who have succeeded in producing solutions of ergot for hypodermic use which do not seriously hurt nor

cause local inflammation when properly injected with an aseptic syringe. It is so difficult for the physician to make his own solutions with assurance of their being absolutely sterile, that it is generally preferable for him to employ the best solutions made by pharmaceutical houses, which are now marketed in small and convenient containers.

It only remains for me to suggest a method of practical application of the principles laid down in treating an individual case.

I will first mention the method which I have been accustomed to use. The first step is to wholly and immediately discontinue the use of the narcotic and place conditions about the patient which will absolutely prohibit access to that drug, or to any other that would be regarded as a substitute. By this method I demonstrate the most clearly to the subject what he is loath to believe, viz.: that neither the drug he has been using, nor any other of similar effect, is necessary to him. I at once begin the application of ergot, because I know that within from twenty-four to thirty-six hours, there will begin, in the extreme cases, a violent reactionary stage, the basis of which will be a dilated state of the blood vessels in the nerve centers, which may be modified by the action of ergot upon their muscular coat. At the same time I give a mercurial purgative followed in a few hours by a sufficient saline to assure prompt purgation. This is desirable in order to limit or avoid the irritative effect of a loaded bowel upon an irritable and excited brain and cord; and also to prepare the digestive tract for especially good service during the coming exhausting ordeal. In preparation also against exhaustion, I discontinue the ordinary meals and give abundant fluid and easily digested nourishment every three hours, such as a good form of beef, and the best of which I know is a paste, consisting of the ordinary fluid extract to which has been added the desiccated and pulverized fibrin. This form is therefore not wholly soluble, the fibrin settling to the bottom if not constantly stirred. The whites of a couple of eggs dissolved in half a glass of cold water, to which a pinch of salt has been added, make another good three-hour-interim meal as do also some of the cereal or lactocereal preparations on the market. With the exception of the egg food it is better to give all these liquid foods quite warm or hot. Do not use nutritives prepared with alcohol. The bowels must be kept open at least once a day, better two or three times, and I prefer the fluid extract of *Rhamnus frangula* for this purpose, in doses of one or two drams at bed-time and perhaps also forenoon and afternoon. The frequency of application of the ergot will depend upon the degree of addiction, and upon the general condition of the subject when the drug was discontinued. The larger the daily dosage had been and the greater the nervous prostration at the beginning of the treatment the greater is likely to be the reaction following the discontinuance and, therefore, the greater should be the effort to prepare against this reaction. In general, the range would be from two to three doses per diem to one every two hours in the extreme cases, a dose being one-half dram of my solution* or of Squibb's new extract of ergot for hypodermic use, the two solutions being approximately the same. In all that I have said I have kept in mind the most difficult of all the drug habit cases to successfully treat, the morphine habitués. As compared with these the worst of the alcoholic class is simplicity itself, if ergot is properly used. The so-called "gold cure," to use a slang phrase, "is not in it" as compared with the ergot cure and, no matter what the degree of addiction, I would not for a moment consider the plan of "tapering off." The extreme case of morphine habituation which I mentioned occurred twenty years ago and had I then known and applied what I now know of ergot therapy, I am quite sure that that "twenty-four hours" would have had a very different history, and I would not hesitate to-day to treat such a case in any well-regulated hospital. One fact in my experience with ergot in treating the habit cases is worth mentioning, viz., that in no case after the first forty-eight hours have I ever had a request from the subject for his drug or a substitute, nor have I seen in any case any evidence of such desire. I have repeatedly been asked by a doctor-subject what under the sun I had been giving him (supposing, evidently, that I had used a substitute) as he had not had an ill feeling.

I have said that there are other methods of securing the prime indication in these habit cases and I would advise combining one or more of them with the ergot treatment, especially in the extremer instances.

It is desirable to avoid using in treatment any of the narcotic or even hypnotic class of drugs. Sleep is one of the requisites, but it may be secured without those drugs and I would do so if I had to use all five of the therapeutic agents I have mentioned and that they will suffice I have no shadow of doubt. I am so radically opposed to the "tapering off" plan of treating the habit classes that I hesitate to make any suggestion that savors of it, yet I am persuaded that there are many excellent practitioners of medicine who would not persist through the first forty-eight or sixty hours in carrying out my plan of treatment, with a confirmed, large user of morphine, and that it would be better to apply a modified treatment from the beginning, than to begin with the radical treatment and resort to the drug during the crisis of nervous excitement and physical depression. As my method has reference chiefly to the moral effect upon the subject, I will suggest a plan by which this may still be secured though the subject has the benefit of a modi-

* Take Squibb's solid extract of ergot ʒj, dissolved in sterilized distilled water ʒj. After filtering the solution add two minims of chloroform and shake gently. This solution is the most satisfactory I have used. It should be made with every precaution to secure against sepsis.

fication which will avoid, wholly or chiefly, the extreme reaction. This is to apply only to the worse cases of morphine or opium addiction, as alcoholic and other classes do not require such modification. The modified plan is to give with two of the hypodermics of ergot, each day, a fractional part of the quantity that had been daily consumed, and one-tenth part will be found sufficient if the ergot is given often enough. For example, if ten grains per diem had been used, one of the morning hypodermics of ergot would contain one-half grain of morphine and the same quantity would be given with one of the evening doses of ergot. The second day the morphine would be reduced to one-quarter grain in each of the two morphine-ergot hypodermics and a similar reduction should be made of 50 per cent. each day of what had been the previous day's dosage until the eighth day, when the morphine should be discontinued. The use of the ergot should be continued two or three weeks after the discontinuance of the morphine, gradually lessening the frequency of administration, to secure permanency of the improved tone of the circulation. The fact of the administration of morphine with the ergot need not and should not be made known to the subject. In these extreme cases, it is especially important that some or all of the other measures suggested be used to aid in correcting the general circulation and restoring tone of the nerve centers. One other suggestion occurs to me, viz., that the phthalate of morphine be used in preference to any other salt of morphine, as I have found it peculiarly free from unpleasant reactionary effect.

The general course I have outlined for the treatment of drug habit cases is presented because I have demonstrated it to be successful and because I believe it to be a rational and commonsense method and the most likely to result in permanent benefit to the thousands whose slavish addiction to drugs is more dreadful than death.

SUTURE OF THE OMENTUM TO THE PARIETAL PERITONEUM (EPIPLOPEXY) FOR ASCITES.

BY JOSEPH H. BRANHAM, M.D.,

OF BALTIMORE, MD.;

PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY AND ABDOMINAL SURGERY, MARYLAND MEDICAL COLLEGE, ETC.

The history of cirrhosis of the liver with ascites is usually progressive with fatal termination in nearly all cases. The abdominal effusion is one of the most distressing symptoms and has much to do with the fatal result. The effusion is caused by the pressure on the portal veins and capillaries in the liver and to secondary changes in the blood, due to want of function in this important organ. Possibly the engorged veins forcing the blood through the contracted liver hasten the degenerating processes in this organ. In old cases of this trouble adhesions are often seen between the omentum and parietal peritoneum.

These adhesions contain many large veins showing that this is an effort of nature to establish a collateral circulation and relieve the obstructed portal system. The formation of these adhesions is no doubt often facilitated by tapping, but they are frequently found in cases that have not been tapped.

These observations led Talma, of Utrecht, to suggest the operation of Epiplopexy for the relief of these cases. The first operation was done by Van der Meulen, of Holland, in 1889.

Several other of the earlier cases were reported from that country but none of them were successful. During the past eleven years many cases have been reported, with varying results. Gaston Torrence (*Annals of Surgery*, 1902, p. 303) collected 28 cases, of which 10 ($35^{72}/_{100}$ per cent.) were cured, and 2 ($7^{13}/_{100}$ per cent.) were improved. My case was Mrs. L., white, aged sixty years, wife of a saloon-keeper. She had used beer freely for a long time and for several years past has been in poor health, suffering from "liver trouble" and indigestion. I saw her early in February, 1903. Her abdomen was enormously distended; she was helpless and could move with great difficulty. Her limbs were edematous and her skin had a muddy yellowish appearance. She had not been tapped. An operation was suggested and readily accepted by the patient. She entered the Franklin Square Hospital and was operated on February 12, 1903. About 6½ gallons of slightly blood-stained fluid was removed. On opening the abdomen the peritoneum was seen to be greatly engorged; the liver was found to be slightly nodular and about half its normal size. The omentum was adherent to the parietal peritoneum on each side, the adhesion being very vascular. Its middle portion was sutured to the abdominal wall on each side of the incision and a gauze drain was inserted. Large quantities of fluid came away and the edema of the feet and limbs disappeared during the first two days.

At this time the drain was removed, and the wound soon closed. Although there was no indication of infection at any time, the patient ran an irregular temperature for more than three weeks. The morning temperature being usually subnormal, while the afternoon temperature was slightly elevated. The patient's general condition was always satisfactory, and her improvement was marked.

For six months after the operation her health was better than it had been for years and she was actively engaged in her household duties. Two weeks ago she began to complain of slight pain in her left thorax and from shortness of breath.

Dr. H. C. Bubert, her physician, diagnosticated pleural effusion. I saw her with him, and on September 22 we aspirated her chest, drawing five quarts of bloody serum. Her abdomen presented a peculiar appearance before the operation. There was no distention of the lower part but on the left side of the median line below the costal arch was a hard mass, evidently the left lobe of the liver pushed down and forward.

September 23.—The patient much improved; still slight fulness over the lower left thorax; the left lobe of liver in its normal position, and careful examination failed to show any sign of ascites.

Some observers think that the ascites of liver cirrhosis is due largely to blood changes secondary to the liver degeneration. If this be true and the pleuritic effusion in this case was the result of such changes, the absence of recurrent peritoneal effusion speaks strongly for the operation.

The possibilities of this operation are limited by the liver condition. In cases where the cells of this organ are so far destroyed that its functions are lost; the result is fatal and the operation necessarily a failure. It is only in the less common cases, where the destructive processes can be arrested, that we can hope for a cure.

In others, where the degeneration is slow, the patients may be relieved. Several modifications to this operation have been suggested. Curetting and suturing the liver and other solid organs to the abdominal wall has been advised by some. These procedures seem to me to add danger to the cases without benefit. These patients have little resistance and readily become infected; the exudate from the irritated surfaces forms an excellent culture medium for germs, and the cases operated on by this method show a high mortality. It seems probable that irritation of the liver wall resulting in adhesion would be more harmful than beneficial.

The primary object of the operation is to relieve the congested liver, and irritation or suture of its coverings is not likely to bring about this result. Simple suture of the omentum with gauze drainage, it seems to me, gives the best results with the minimum amount of danger.

The case reported shows several points of especial interest: (1) The presence of the vascular adhesion showing the effort of nature to form collateral circulation; (2) the subsequent occurrence of pleural effusion with no ascites points strongly to good collateral circulation for the portal system, and (3) the marked improvement in the patient's general condition shows better functioning of the liver and intestinal organs after the operation.

Bacteriology of Eczema.—In a large number of cases of chronic eczema, F. Veiel (Münch. med. Woch., Jan. 5, 1904) found staphylococci in all stages. The colonies were generally characteristic for the aureus, less often for the albus and citreus; occasionally several were present together, though the colonies were as a rule pure. The germs were in every way identical with the common pyogenic cocci and not with the staphylococci of the normal skin. The part which staphylococci play in the pathology of eczema cannot be decided with our present knowledge, but the fact that they occur in early stages and in pure culture, seems to indicate some important rôle in the pathogenesis of the process. Since other germs are absent as has been described by Unna can be positively excluded and eczema must hence be looked upon as a form of pyogenic skin disease.

MEDICAL PROGRESS.

MEDICINE.

The Sun as a Cause of Disease.—In these days, in which so much is being written of the stimulant and beneficial action of the actinic rays of the sun, it is but natural that the reverse of the picture should also find its painter. Finsen, indeed, who has been the pioneer in the therapeutic application of these rays, was also the one to initiate the reaction, by his studies on smallpox and light, and on sunburn. Prof. Fermi (Arch. f. Hygiene, 1904, Heft 4) has pursued this latter line of investigation experimentally, upon a large number of human subjects and with most interesting results. By exposing his "material" to the direct sunlight for varying periods of time he was able, in a large percentage of cases, to produce the following set of symptoms, which often persisted over many days: Cephalalgia, dryness of the nasal mucosa, snuffling, coryza, pharyngitis, weariness, slight conjunctivitis, dryness of the lips, fever, pseudo-influenza, constipation, insomnia, epistaxis, various pains. This congeries of symptoms seems not very formidable, yet it induces the author to conclude, from the observed coincidence of meteorological conditions and of certain diseases, that exposure to the sun's rays is a predisposing factor in coryza, influenza, hay fever and epidemic meningitis. A curious element is the fact that only 53 per cent. of the persons under experiment, found the exposure disagreeable, while the others, notwithstanding the subsequent ill effects, enjoyed it.

Acute Polyomysitis.—Acute inflammation of one, or a group of muscles, is a rare condition, which may for a time simulate an infectious disease. In the case of J. Baer (Münch. med. Woch., Jan. 26, 1904), a lobar pneumonia was first suspected, but soon the pulmonic symptoms disappeared and the muscles of the shoulder region became acutely inflamed. The onset was with a distinct chill and throughout the course fever and tenderness along the nerve-trunks, without other signs of neuritis, were marked symptoms. Antipyrin and the salicylates were without effect. All attempts to isolate a specific germ were unsuccessful since culture taken from the fluid aspirated from the muscles, and the blood itself remained sterile.

Acute and Chronic Inflammations of the Sigmoid Flexure.—Acute sigmoiditis is a condition which has been observed repeatedly by A. Bittdorf (Münch. med. Woch., Jan. 26, 1904), and which manifests itself by fever, pains in the left hypochondrium and a distinct tumor in this region, of elongated shape, with constipation and more or less distension of the entire abdomen. The cause is probably an accumulation of feces in the folds of the gut. High leucocyte counts obtained in a few cases make it probable that a circumscribed peritonitis may follow. The treatment calls for rest, fluid diet, Priessnitz and cathartics; as soon as the bowels are emptied, relief generally sets in. In the chronic form the symptoms are the same but more prolonged and with less marked fever and the patients often complain of anorexia, lassitude and general nervous disturbances. The treatment is the same; occasionally massage gives much relief.

Multiple Fat Necrosis.—There is a close relation between fat necrosis and lesions of the pancreas, yet very marked cases have been described without the slightest suggestion of pancreatic disease. The most important of the latter is hemorrhagic pancreatitis, though its most acute form usually kills so rapidly that necrotic foci do not have time to form. Except in traumatic cases, the appearance of fat

necrosis seems to be limited to a certain age and to stand in close relation to the amount of panniculus adiposus so that stout individuals of advanced years are most often affected. The best way to demonstrate the foci is by means of the mordant for gliafibers, which contains chrome-alum and acetate of copper; the latter will combine with the fat and give rise to a green color. This is not, however, specific for fat necrosis for fatty areas, such as atheromatous spots on the intima of the aorta, will also turn green, according to C. Hart (Münch. med. Woch., Jan. 12, 1904). The etiology of fat necrosis is still obscure, but it is generally conceded that pancreatic juice escapes from the inflamed pancreas and that its fat-splitting ferment liberates fatty acids which combine with lime salts. The clinical symptoms are uniform: there are signs of intestinal occlusion or perforative peritonitis or else severe colic and collapse develops so that an intoxication or severe infection is suspected. The pathological lesions do not explain the symptoms, which may possibly depend on irritation of the sympathetic nerves. All therapy is without avail, yet cases of spontaneous cure are on record.

Occurrence of Koplik Spots in Measles.—In a severe epidemic of measles, O. Müller (Münch. med. Woch., Jan. 19, 1904) found the Koplik spots present in 81 per cent. and an initial eruption on the hard palate in 86 per cent. It was only possible to observe 12 cases during the period of incubation; in these the spots were found seven times on the first day of the disease, when the temperature began to rise, when the eruption on the hard palate usually did not show itself before the third day. The author also had occasion to observe an epidemic of rubeola in which almost half of the cases presented typical Koplik spots, so that these can no longer be considered pathognomonic for measles. The diazo reaction in the latter disease was also studied; it is very constant in appearance but is of less practical value since it is rarely positive before the end of the first stage or the beginning of the second. There seems to be considerable difference of opinion as to the temperature curve in measles; in most cases seen by the author from the very start, there was an initial rise, then an intermission of one to two days, and finally a continuous fever of several days' duration. In two instances the temperature rose with a remittent curve and in one the onset was sudden, with high fever.

Eosinophile Cells in Sputum.—A good method for demonstrating the eosinophile cells in sputum is given by W. Hildebrandt (Münch. med. Woch., Jan. 19, 1904). He spreads the particles of sputum on a slide, heats this and treats it for thirty to sixty seconds with ten drops of Leischmann's eosinmethylene-blue solution. Fifteen to seventeen drops of water are then added to the dye and the whole allowed to remain on the slide for seven to nine minutes more. The slide is finally washed, dried and examined with the oil-immersion. It is a mistake to believe that the presence of many eosinophile cells has a special diagnostic value since they are found in abundance in many diseases of the respiratory tract. In tuberculosis of all varieties they may constitute up to 80 per cent. of all cells and they often abound in the sputum of acute and chronic bronchitis, bronchopneumonia, lobar pneumonia and hemorrhagic infarct of the lung. They also occur in nasal and pharyngeal secretion without the presence of asthma and in the vaginal secretion of gonorrhea. In asthma, however, the granules are larger and more distinct and take a deeper stain, yet these peculiarities are not sufficiently marked to enable a diagnosis.

Tachycardia in Pulmonary Tuberculosis.—Tachycardia during the course of infectious diseases is generally due to weakness of the heart muscle, and this applies to tuberculosis as well. There is, however, an increased pulse-rate during the early stages where fever is still absent, which evidently has a different causation and which is frequently of importance as an early symptom. S. Sterling (Münch. med. Woch., Jan. 19, 1904) states that it also has a high prognostic value, so that the following rules may be laid down: (1) A normal pulse-rate in the course of pulmonary tuberculosis is a very favorable sign. (2) Constant tachycardia renders the outlook more serious, in direct proportion to the degree of increase, especially if fever is absent. This applies particularly to the first stage of the disease. (3) Nervousness on part of the patient will only bring about a temporary increase; even strong psychical influences will only add 5 to 10 beats to the pulse where in the non-tuberculous the increase would amount to 20 to 30 beats. (4). The rules apply to both sexes but do not hold so strictly in children and old people. (5) There seems to be no constant relation to hemoptysis; convalescence from influenza retards the pulse, and rest, cold applications to the precordium and the bromides have the same action in the more favorable cases. (6) With a slow pulse, the outlook is excellent unless some renal or arterial disease, etc., is responsible for the condition.

OBSTETRICS AND GYNECOLOGY.

Extra-uterine Pregnancy.—It may be admitted that the profession is now in fair possession of the facts related to the pathology of extra-uterine gestation. The symptomatology, however, and, above all, certain details of the treatment, are still largely in need of elucidation, and an experience of more than 18 cases, as reported by M. Storer (Bost. Med. and Surg. Jour., Jan. 7) is well worthy of attention. This author has had an especially valuable experience with tubal abortions, inasmuch as this condition, ordinarily considered so rare, occurred in 56 per cent. of his cases. The symptoms which he found of chief importance in this condition were pain and anomalous escape of blood from the uterus. This pain is characteristic, yet ordinarily not severe enough to bring the patient to a doctor. It is quite different from that of ordinary menstruation, short-lived, stabbing, not colicky, and not comparable in severity with the pain of a tubal rupture. The subsequent metrorrhagia ordinarily excites the suspicion of the patient, which is confirmed by a vaginal examination. As regards tubal abortion or rupture, the author states that the characteristic symptoms, contrary to general belief, occur before the eighth week. The question of treatment resolves itself into one of operation; the author advises that this should always be as early as possible after diagnosis.

Intra-uterine Flushing and Drainage.—As a substitute for the curette and douche in the treatment of puerperal sepsis, H. G. Wetherill (Am. Med., Jan. 30, 1904) proposes the employment of a double drainage tube and frequent irrigations with weak alcohol. A soft rubber tube of the proper diameter is doubled on itself so as to form a triangular end. The removal of putrescible débris from the uterus is accomplished by the finger or a blunt placenta forceps, followed if necessary by flushing with salt solution, potassium permanganate or diluted alcohol, all of which are non-toxic and used only for

their mechanical effect in washing out loose fragments. The double drainage tube is then inserted to the uterine fundus, the vagina lightly packed with gauze, no anesthetic being necessary. The tubes are then flushed out every two to four hours with alcohol, varying from 25 to 95 per cent. in strength. The author considers that the omission of any gauze packing in the uterus is very important and the diluted alcohol used for flushing the tubes, in addition to its mechanical effect in removing débris, has a chemical action in arresting putrefaction and bacterial growth. It is non-toxic and also supporting and stimulating.

Rupture of the Uterus During Labor.—Happily this is a very uncommon accident. T. B. Grimsdale (Brit. Jour. Obstet., Dec., 1903) finds that its frequency varies according to various authors from 1 to 482 cases (Collins) to 1 to 6,000 (Lusk). The mortality is also very high, varying between 55 and 95 per cent., according to the estimates of authorities. The lowest mortality is obtained where prompt abdominal operation can be performed. A patient who came under the writer's observation had had four children, and her fifth confinement started on June 14, 1903, at 2 P.M., when the "waters" burst. At 9.30 the following evening labor pains began, and continued until a hand (the left) presented. Version was done, but as the os was rigid there was some delay. The child was dead and putrid. When the operator tried to get the foot down through the os, it was recognized that something was wrong, for at the posterior portion of the os another opening could be felt, and through this there came what the accoucheur considered a loop of the intestines. The delivery was completed and after the vagina had been packed with gauze, the patient was removed to the Royal Infirmary where she arrived at 3 o'clock the next morning. The abdomen was opened as soon as possible and there escaped from its cavity clear fluid and blood clots. The uterus was found to be ruptured in the posterior portion of the lower uterine segment. Panhysterectomy was performed. The patient was much collapsed after the operation. On June 28, one week after the operation, the patient acquired pleurisy, which cleared up in four days, and on July 21 she was discharged as cured. The author believes that the safest treatment in the long run will be found in the boldest measures; also, that it is safer in these cases to remove the entire uterus.

Hydatiform Mole.—The patient in whom this condition developed had had one miscarriage and three children, and when she reached her fortieth year in March, 1901, she had missed her last period. On April 9 she had a severe hemorrhage. Five days later there was a second one, and still five days later, the third; large clots being passed on each occasion. The patient had nausea, and vomiting and on examination, there could be made out a large abdominal tumor resembling in size and shape a pregnant uterus, but which had enlarged much more rapidly than a pregnant uterus should. Jno. D. Malcolm (Brit. Jour. of Obst., Dec., 1903) examined the patient and found the uterus enlarged, but the cervix was hard and firm. As neither fetal heart nor uterine souffle could be heard on auscultation, pregnancy was ruled out in making a diagnosis of the condition. May 8 Dr. R. H. Bell had the patient anesthetized. On introducing the finger through the cervix, a soft mass, which did not bleed freely, was felt, but there was no trace of membranes or fetal parts. A small piece of the mass was dragged out and proved to be the characteristic small cysts of a hydatiform mole. The uterus was emptied and curetted. At this time there was no suspicion of the presence of any abnormal condition outside the uterus. May 29, after the patient had had a tedious convalescence, a second operation was decided upon because the patient had had a great deal of abdominal pain, especially upon the right side of the pelvis. Dr. Malcolm opened the abdomen and a cystic tumor of the right ovary was found, which was as large as a cocoanut. On the left side there was a similar but very much smaller growth. The pedicle upon the right side was twisted, causing, no doubt, the previous abdominal pain. The uterus was large and flabby and not of the same consistence throughout. It was found to be invaded by a chorio-epithelioma. A complete hysterectomy was performed. The patient left the hospital on July 8, forty days after the last operation. A letter received from the patient on April 4, 1903, reported that she was in excellent health. On June 20 of that year, a physical examination by the author showed all parts of the pelvis perfectly healthy.

Acute Contagious Pemphigus Neonatorum.—It is rare to find this disease occurring as a limited epidemic unless it be of syphilitic origin. When it does occur, it is local in its distribution, among the poor, and is associated with unclean linen and want of antiseptic precautions. In September and October, 1902, an outbreak of this peculiar infection sprang up in the Richmond (Surrey) Lying-in Charity Hospital. According to George J. Maguire (Brit. Jour. Obst., Dec., 1903) there were 18 infectious out of 20 cases delivered by one midwife; and when she left the neighborhood the epidemic ceased. Of these 18 cases, eight died. The symptom common to all the cases was the skin lesion; nor was there any other manifested in those infants that recovered. In all the fatal cases, there had been other signs, forming a group of easily recognizable and similar symptoms; the whole composing a clinical picture of definite outline. The bullæ, after breaking down did not dry up or pale, but remained constantly moist until the death of the infant. There were also symptoms of an acute toxemia in the fatal cases. The epidemic was found to be due to infection by a pathogenic organism, the *Staphylococcus pyogenes aureus,* convey from case to case by the infected midwife. Although only fatal among the new-born older children and adults were attacked during the epidemic. It was characterized by a bullous eruption of the skin, variable in distribution and extent, the specific micro-organism being found in the contents of the vesicles. The point at which the systemic invasion took place was the unhealed umbilical scar. Treatment to all appearances had little or no effect upon the course and duration of the disease, whatever the final outcome of the case.

Acute Yellow Atrophy of the Liver with Pregnancy.—The following case, which is most interesting, is reported by A. J. Sturmer (Brit. Jour. of Obst., Dec., 1903). Woman, aged thirty-five years, II-para, was admitted into the Government Maternity Hospital at Madras, in a semiconscious condition. She was said to be six months pregnant. Her urine was of high color, sp. gr. 1.015, and acid, but contained no albumin. With a drop of nitric acid no decided bile reaction was present, but on the evaporation of the acidified urine leucin crystals were present. Abdominal examination showed no uterine action and the liver dulness seemed to have disappeared; the hepatic area was resonant all over. Her bowels did not act, and after a restless day she became noisy, and died twelve hours after admission. A post mortem was made nine hours after death. All the tissues were bile stained. Liver shrunk under the ribs and folded on itself and wrinkled; tissue very soft, not yellow, and more like that of the spleen; no

lobules apparent; weight 23 ounces. Gall-bladder empty, except for a little thick gray mucus; ducts all pervious; uterine wall thin, and the placenta attached to right and front, amniotic fluid greenish yellow in color. Intestines not injected. Bladder contained a good deal of very yellow urine. Section taken from the surface of the liver showed that the liver structure was gone; it was only an ill-staining mass of débris, pigment and fatty granules. Those cells, which were not completely disorganized, showed an indistinct outline, being granular and contained a large amount of pigment, which completely obscured the cell nuclei. This pigment was a very marked feature of the specimen. Acute yellow atrophy of the liver during pregnancy is quite rare. From 1883 up to present time, 37,475 labors and abortions were treated at the Government Maternity Hospital in Madras, and during that period, but five cases of this disease have been noted. In 1886, two cases were recorded. The writer gave the patient under consideration, thyroid extract on the supposition that the disease was one due to perverted metabolism, but, of course, no results could be obtained, as the patient so rapidly succumbed.

Antenatal Rigor Mortis.—Medical jurists can no longer doubt that this condition may and does take place before the expulsion of the fetus from the uterus; and, says KEDARNATH DAS (Brit. Jour. of Obst., Dec., 1903), that its presence in the new-born infant is not necessarily proof of life apart from the mother—of, in fact, an independent existence. In all there have been 39 such cases reported. The rarity with which it has been observed may be explained by the following circumstances: (1) The fetus has probably gone through the rigid stage before birth; (2) the obstetrician generally remains busy with the mother; (3) out of respect to the relatives and friends of the patient, the doctor does not like to critically examine the fetus after it has been found dead; (4) probably the attention of very few obstetricians is directed to this point. In a case of the author's the fetal movements had been most violent, but half an hour later no fetal heart sounds were audible. The writer is inclined to believe that prolonged gestation after the period when labor comes on spontaneously, may be an important factor in the production of antenatal rigor mortis.

Permanent Results from Prolapse Operations.—An interesting series of statistics is presented by M. JACOBY (Arch. f. Gyn., Vol. 70, No. 3) relating to 257 cases of uterine prolapse treated by various operative procedures. About 77 per cent. of these could be traced for the purposes of the investigation. As far as possible the choice of operation in each case was governed by the actual conditions seemed to demand rather than by favoring any particular procedure which might happen to be in vogue at the time. The author, as the result of his observation, became convinced of the truth of the proposition already advanced by Küstner, that in every operation for uterine prolapse it is most essential to correct whatever displacement may exist of the uterus itself. He comes to the conclusion that no one method can be recommended for all cases, each case must be treated individually. Prolapse of the posterior vaginal wall due to old lacerations can in most instances be corrected by a perineorrhaphy after the method of Asch without doing a separate colporrhaphy. If the anterior wall is prolapsed, an anterior colporrhaphy must be added. Recto- and cystoceles demand particular attention. If the prolapse of the vaginal walls is accompanied by a retroflexion or a retroversion, this should invariably be attended to. He prefers the Alexander-Adams operation for bringing the uterus forward and where there is a high degree of prolapse in women after the climacteric, recommends a vaginal hysterectomy, together with the necessary plastic operations on the vagina. Permanent results in his series of cases comprised 94.53 per cent. of all women examined, after a sufficiently long time to test the success of the operation. These figures are much more favorable than those presented by other authors, which range from 69 to 79 per cent.

Puerperal Metrophlebitis.—A number of surgeons have recommended and carried out with more or less success, a method which consists of ligating or excising thrombosed veins due to puerperal pyemia. Trendelenburg adopted an extraperitoneal approach to the hypogastric vein and reports a successful case. Sippel recommended, in cases where the uterus was removed for pyemia, that the neighboring veins be followed up and excised, this of course by the abdominal route. The former advises doing the operation after the second chill, the latter not until the chills have recurred several times. Trendelenburg thinks it is essential that the hypogastric vein should be ligated, because in a series of 21 autopsies on cases of thrombophlebitis, he found the hypogastric involved about twice as often as the spermatic. GROSSMAN (Archiv f. Gyn., Vol. 70, No. 3) has lately made a more extensive series of autopsies in order to determine the relative involvement of these veins. Among 51 cases there were 14 with thrombophlebitis, 24 with lymphangitis and 13 in which both forms were combined. He also found that in the majority of cases other veins besides the hypogastric were thrombosed. In only one case could the operation advised by Trendelenburg have been done. A previous diagnosis had only been made in nine instances. The course of the disease in all cases where there is a simple thrombophlebitis is a protracted one, lasting several weeks or months, while in the majority of cases where a lymphangitis is present the fatal result comes on in a few days. Another noticeable feature in this series of 51 cases was the fact that in all some divergence from the normal course of labor was present. The author does not believe that the mortality in puerperal pyemia will be much affected by the introduction of this operation, but thinks that the effort is a step in the right direction and further research should be encouraged.

NEUROLOGY AND PSYCHIATRY.

Musical Equivalent of Epilepsy.—TEOFILO MONTAGNINI (Gaz. degli ospedali, Dec. 27, 1903) reports two cases in which a musical equivalent of epilepsy was observed. The history of his own case was that of a man aged forty-eight years, subject to epileptic attacks. Physically he was normal; mentally somewhat weak, querulous and excitable, and sometimes subject to mild delusions of persecution. From 1892 to 1896 he suffered from typical epileptic attacks, with mental deterioration, and occasional spells of echolalia. In 1896 he presented the phenomena of ambulatory automatism. In 1897 his mental condition was at times somewhat demented. He began to suffer from attacks of singing, which began and ended suddenly, lasting five to ten minutes, at which time he was insensitive to pain or touch. He never had convulsions during the song, though marked pallor and a slight trembling were noted. These attacks of singing were improvised and spontaneous; not caused by external stimulus. In 1898 he alternated attacks of singing with general convulsions, both of which occurred more frequently than formerly. Treatment by bromipin, continued to 1902, completely stopped the motor convulsions, and made the attacks of singing much less frequent. The writer does not believe these musical crises were related to the de-

mentia, because they occurred at the same time; they always were the same in character, and lasted about as long as grand mal—five to ten minutes. They persisted and the patient was not unconscious during the attack. The general tremor, pallor and anesthesia to pain during the attack was remarkable, and their subsidence under bromides was marked.

Diagnostic Significance of Certain Reflexes and Tendon Phenomena.—The importance of certain tendon and skin reflexes in determining the presence of organic disease is being more fully realized not only by neurologists but also by those who come in contact with general medical cases. H. Oppenheim (Med. Rec., Jan. 2, 1904), whose experience in a clinic for nervous diseases in Berlin has brought him in contact with so many thousands of cases in which the knee-jerks were carefully examined for, makes the statement that he has never seen more than three or four instances of complete loss of knee-jerk when some organic disease of the nervous system was not present. These very few exceptions would seem to prove the rule. Mechanical conditions may sometimes render the demonstration of this reflex difficult or impossible. Obesity and joint deformities must, of course, be taken into consideration. He urges also the importance of the heel phenomenon, or plantar flexion of the foot upon sticking the tendo Achilles. This has not been held to be of much value on account of its supposed inconstancy in healthy individuals, but he believes that if the examination is made with the patient in a kneeling position the reflex can be regularly elicited. The absence of this phenomenon may depend upon neuralgias, sciatica, deformities, alcoholism, and diabetes and even in apparently healthy people it is sometimes absent, but on the other hand, it is of great importance, and in tabes may disappear before the knee phenomenon. The significance of Babinski's reflex has also been thoroughly investigated and for a time was thought to mean an increased tonicity such as exists in a spastic paraplegia, the pyramidal tracts being involved. It has been found, however, that it does exist in many cases in which there is also an involvement of the posterior columns of the cords and areas of the nervous system which exerts an influence antagonistic to the symptoms from pyramidal tract diseases alone. This phenomenon may then be the only remaining sign of pyramidal lesion. When this tract is involved in the brain, as in hemiplegia, Babinski's sign is, as a rule, present, but lesions of certain other tracts and centers at the same time may prevent its appearance. In the first year of life the sign is also present because the pyramidal tracts are yet undeveloped. In certain cases of epilepsy the sign has also been demonstrated so that we must not conclude that its pressure always means an organic lesion of the pyramidal tracts. The author also alludes to a reflex which he first observed and which is similar to Babinski's in importance, but which may sometimes be demonstrated when the latter is absent. If, in a normal person, on stroking the inner side of the leg from above downward, with the thumb or by pinching a fold of skin on the inner side of the leg, either no reflex movement will follow or a plantar flexion of the toes will follow. In affections of the pyramidal tracts a dorsal flexion of the toes and foot is observed. In this reflex not only the extensor longus hallucis but also the tibialis anticus and sometimes the extensor communis digitorum contract.

The Presence and Significance of Cholin in the Cerebrospinal Fluid in Epilepsy.—Ever since Mott and Halliburton discovered this alkaloid in the blood and cerebrospinal fluid of cases of nervous disease, the relationship of this substance to the pathogenesis of lesions of the nervous system has been carefully studied. Found by the original investigators in progressive paralysis and tabes, combined and disseminated sclerosis, alcoholic polyneuritis, beriberi and after experimental section of the sciatic nerve, this alkaloid has also been discovered in the cerebrospinal fluid of epileptics by J. Donath (Hoppe-Seyler's Zeitsch., Oct. 31, 1903), who finds that not only is it present in such cases as a rule, but that it also is capable of producing convulsions if injected into animals. It is remarkable that in genuine Jacksonian and syphilitic epilepsy, the evidence of the presence of cholin is as positive as in organic diseases of the central nervous system, in which the presence of cholin is to be attributed to the disintegration of nerve-tissue with the setting free of lecithin and the splitting off of cholin. On the other hand the author found no cholin in cases of simple hysteria, hystero-epilepsy and neurasthenia. It appears that cholin is burnt up in the blood, for if injected into the brain or into the veins, its presence cannot be detected afterward in the urine. The author injected cholin into the cerebral cortex with the result of producing severe tonic and clonic convulsions that frequently terminated in paresis. The convulsions were mostly general, yet frequently they predominated on one side. In experimenting in the same way with neurin, the author found no appreciable qualitative or quantitative differences between the two substances. Both are powerful nerve-poisons, having a more effective action upon intracerebral than upon intravenous injection. The author is of the opinion that in epilepsy two causative factors are at play, namely, an increased excitability of the cerebral cortex and the operation of some toxic substance. The fact that cholin is found in the cerebrospinal fluid in this disease as in organic diseases of the nervous system, and also the experimental proof of its action when injected into the body, led him to conclude that cholin plays an eminent rôle in the production of the epileptic seizure. At the same time the brain of epileptics is, as the result of hyperemic, chronic inflammatory or hypoplastic processes, more susceptible to the action of such toxins. In this way may probably be explained the epileptiform attacks in progressive paralysis, in which cholin is produced, and in which hyperemia causes an increased excitability of the cortex of the brain.

The Uses of Lumbar Puncture.—A summary of the technic and the clinical and therapeutic advantages of the lumbar puncture is made by C. M. Campbell (Rev. of Neurol. and Psych., Jan., 1904). The puncture is best made in the fourth lumbar interspace, where the dura mater is most firmly attached and where there is thus less chance of the membrane being pushed onward by the needle and failing to draw off fluid. The fourth interspace is determined by feeling for the highest point of the crest of the ilium on both sides; the line joining these points passes over the fourth interspace. Normal cerebrospinal fluid is clear as crystal. If the fluid withdrawn by the operation is bloody, one has to determine whether the blood is caused by the operation or not. There are a number of methods of finding this out, one being that devised by Sicard, namely, that of noting the intensity of the color of the fluid removed; if the blood is due to a hemorrhage, the fluid has a darker tint than if the blood is due to the operation. A greenish or yellowish coloration is seen in chronic jaundice. Of clinical value is the estimation of the osmotic tension of the fluid. Two methods for this purpose are available, the cryoscopic and the hematolytic. The freezing point of blood serum is 0.56°, while that of normal cerebrospinal fluid is about 0.75°. The fluid therefore has a greater molecular concentration than blood serum—is hypertonic with regard to it. This hyper-

tonicity is inverted in cases of acute meningitis. The inversion, if present, confirms the diagnosis of meningitis; if absent, does not exclude it, and in any case does not help to distinguish between the tuberculous and the non-tuberculous form. Bacteriological examination of the fluid often reveals the presence of a meningitis where no clinical symptoms may be present. One has no right to deny, according to Widal, that a case has not been tuberculous meningitis merely because it has recovered, unless inoculation of a guinea-pig with the fluid has proved negative. Bacteriological examination also enables one to subdivide the various forms of non-tuberculous meningitis into (1) epidemic cerebrospinal meningitis due to the pneumococcus of Talamon, the meningococcus of Weichselbaum or the streptococcus of Bonome; (2) the serous meningitis of Ziegler, caused by a variety, among others, by pneumococcus; (3) cases in which Widal has discovered a variety of organisms. In boiling a normal cerebrospinal fluid a slight opalescence and fine threads appear; in certain pathological conditions, as in cases of tabes, general paralysis and syphilitic meningomyelitis and hemiplegia, this opalescence is exaggerated into a turbidity. A similar condition is found in erysipelas of the face, polymorphous erythema, cerebral hemorrhage and secondary syphilis. In acute meningitis fibrin is present. As regards permeability, the normal meningeal covering does not allow potassium iodide to pass through it; this does occur in tuberculous meningitis. The most valuable method of examining the cerebrospinal fluid is the cytological. Normally the cerebrospinal fluid is almost free from elements, containing no polymorphonuclear leucocytes, and few or no lymphocytes. Where there is meningeal irritation this is not the case. Thus in tuberculous meningitis the cells are almost entirely lymphocytes. In acute non-tuberculous meningitis there is usually a marked leucocytosis, sometimes rendering the cerebrospinal fluid purulent. If during chronic nervous diseases the meninges are irritated, cellular elements are found. In general paralysis a lymphocytosis of the cerebrospinal fluid is one of the earliest signs and is practically constant. In true psychoses and dementias of different origin, lymphocytosis is absent. This is also the case in hysteria, neurasthenia and epilepsy. In tabes dorsalis, lymphocytosis is the almost universal rule. The headache, which is such a constant symptom in secondary syphilis, is in certain cases associated with a lymphocytosis of the cerebrospinal fluid. As regards the therapeutic applications of lumbar puncture, it is of value in certain forms of meningitis, in uremic conditions, even with the fluid not under high pressure, and in the headache of secondary syphilis.

The Blood in Epilepsy.—An experimental study having for its object the determination of changes in the blood as a possible cause in the production of epilepsy has been made by F. S. PEARCE and I. N. BOSTON (Medicine, Feb., 1904). The cases studied included only those of essential epilepsy, where there was no organic disease in the brain or any other organs. As no definite histological changes have been noted in idiopathic epilepsy, inherent irritability of the cortical cells remains as an only explanation for the existence of the disease, if we do not think of disturbed metabolism being perhaps the exciting cause, or of some other poison circulating in the blood. Blood studies seem to be of importance therefore, in addition to careful examinations of the urine and other excretions. Observations were made on seven cases as to the number of red and white cells, percentage of hemoglobin, differential leucocyte counts before and after seizures, and also on animals, both before and after inoculation with defibrinated blood of epileptics, with a view of ascertaining the degree of toxicity common to epileptic blood. From these it would seem that there is in idiopathic epilepsy a fairly well marked chlorotic type of anemia. There was also a leucocytosis. The differential count showed a decided reduction in the polynuclear cells, but there was no increase in the lymphocytes, as is the case where the change is induced by malnutrition, starvation, etc. The red cells were approximately normal in number, but there was a moderate degree of poikilocytosis present, and this finding was especially marked where the hemoglobin was greatly reduced. These examinations, therefore, do not reveal any conclusive evidence of a change per se in the cells themselves in the epileptic. Injections were then made into the peritoneal cavity of rabbits, of blood as drawn from the patient and also where it was defibrinated. The results were about the same. In a typical case the hemoglobin rose from 65 to 84 per cent. and then fell to 44 per cent. seven days after the last injection. The leucocytes after several injections rose to the enormous number of 162,800 per cm., previous to which the rabbit was very sick, being rigid and tremulous. This must show some extreme toxic condition of the blood of the person from which it was taken. The leucocytosis disappeared, however, within two days. There were no corpuscular changes noted in the patient, therefore if the blood changes were due to alteration in the blood, it was principally in the serum. The authors believe that presumably some hemolytic enzyme is a part at least of the pathogenesis of essential epilepsy.

Syphilis and Tabes.—In a lengthy communication on this subject, W. ERB (Berl. klin. Woch., Jan. 25, 1904) reviews the statistical evidence which has been brought forward and comes to the conclusion that tabes in the great majority of cases is undoubtedly a disease of syphilitic origin, but at the present time it cannot be definitely proved, although very probable, that this is true in every instance. Among his own series of nine hundred cases, only about three per cent. failed at some time or other to show symptoms of syphilis. He thinks that these may be included under "syphilis occulta." Methods of cytodiagnosis, combined with lumbar puncture, may, in the near future, aid in giving us more definite information. The author believes, however, that there are many doubtful cases where true syphilis was questionably present, and suggests that there may be some other toxin closely related to that of syphilis, possibly of an infectious nature, which may injure the nerve tracts in a similar manner. The final decision of the question must therefore be left to the future.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Toxins and Antitoxins of Fatigue.—After many laborious experiments, D. WEICHARDT (Münch. med. Woch., Jan. 5, 1904) has finally succeeded in demonstrating a toxin of fatigue and its antidote. Since the toxin is most likely neutralized very rapidly in the system, only negative results were obtained when the blood-serum of exhausted animals was injected subcutaneously or intravenously into healthy animals of the same species. More success followed the use of muscle-juice; when injected with absolutely aseptic precautions, the animals died after twenty to forty hours, while the control animals remained alive. The toxins were very unstable and lost their activity when warmed up to 56° C. for two hours; if not warmed, the toxicity increased for forty-eight hours and then

gradually declined and disappeared, even if kept on the ice-chest under toluol. By means of intraperitoneal injection, an antitoxin could be readily obtained. This seems to be very stable and can even pass through the walls of the stomach without being altered.

Dried Immune Sera.—Every bacteriologist who has had to work with the diagnosis of typhoid cultures is aware of the trouble and difficulty connected with the immune sera. It is either necessary to preserve a set of sealed glass tubes containing serum of tested titer, which is broken for every test, or an immune animal must be kept in stock, and bled on occasion. These difficulties have been very ingeniously overcome by E. Jacobsthal (Arch. f. Hyg., 1903, Heft 3), by the preparation of dried and durable sera. Serum of a known titer is evenly distributed, with special precautions, on the surface of a piece of filter paper which has been ruled off into squares of definite and uniform size. By a simple calculation, the "titer" of each of these squares when dissolved in a given quantity of a salt solution may be determined. It is found that the paper has a uniform value, that it retains its power unchanged over long periods, that it is not injured by the cold of the ice-box, nor by heat of 100° F., prolonged for three-quarters of an hour. The utility of the discovery is, therefore, bound to be very great.

A New Method of Determining Albumin.—There is as yet no rapid and accurate method of estimating the amount of albumin in a body fluid. The Esbach is very unreliable and the methods of Kjehldahl, Jolles and the gravimetric estimation entirely too complicated for the ordinary laboratory. E. Reiss (Arch. f. exp. Path. u. Pharmak., Vol. 51, No. 1) has discovered that solutions of albumin possess a definite index of refraction and the percentage can be easily determined by means of a refractometer, with the aid of certain tables. A great advantage lies in the fact that only a single drop of fluid is required. Thus, in the case of blood, it is only necessary to fill the capillary tube of the Fleischl apparatus, then to seal it and to remove the clot after one-half to twelve hours. The drop of serum which remains will be amply sufficient. In a number of cases examined, the albumin of the blood was below normal, wherever the general vitality was reduced, irrespective of the disease from which the patient suffered. In acute infectious diseases there is no evident relation with the course of the infection but more with the duration and the severity of the disease. An amount of albumin less than 6.5 per cent., and in the presence of edema, less than 5 per cent., is a very unfavorable sign. The lowest figures were obtained in nephritis, even without anasarca. The hemaglobin of the blood is generally reduced earlier than the albumin and its estimation is of more value except in the more advanced stages of chronic disease, in acute infections and in nephritis. The method is equally as valuable for exudates, transudates and cerebrospinal fluid, but different tables must be used; for urine, the proper coefficient has yet to be determined.

Influence of Salt on Gastric Secretion.—Salt when given in fairly large doses, invariably causes a diminution of acidity in the gastric secretion and quantities of about seven grams have the same influence in man, according to M. Bönninger (Münch. med. Woch., Jan. 12, 1904). There may be some advantage in the therapeutic use of salt for hyperacidity; it is certainly preferably to sugar, since it does not influence the motility of the stomach to such an extent, though it lacks nutritive value. The digestion of proteids is also inhibited by the chlorides; they share this property with the sulphates, which interfere with digestion even in weak dilution. This does not, however, argue against the use of mineral waters for gastric disorders, as these are generally taken in the morning, on an empty stomach.

Experimental Inoculation of Endocarditis.—A case of fatal subacute infectious endocarditis caused by the pneumococcus was observed by C. Lesieur (Jour. de Physiol., Nov. 15, 1903), in which death was ushered in by a cerebrospinal meningitis. Cultures taken from the blood during life, and from the endocardial vegetations and meninges at autopsy revealed the presence of the pneumococcus. A rabbit inoculated with the pus containing the latter developed vegetations in the mitral valve. A second rabbit inoculated with blood taken from the heart of the first developed similar lesions in the mitral valve. The most interesting fact derived from these experiments is that the pneumococcus may display a tenacity to produce endocarditis in spite of the fact that it has to traverse channels and tissues ordinarily more susceptible to its pathogenic influence, thus becoming a special microbe of endocarditis. This phenomenon is evidently one showing the adaptation of a germ which is frequently a simple saprophyte in the saliva, to produce morbid changes in a special tissue.

Gastric Mucous Membrane in the Esophagus.—If the esophagus and stomach are preserved in Müller's fluid combined with formalin, flat epithelium can be readily distinguished from glandular by the cold; the interior of the stomach will be tinged deep brown while the inner lining of the esophagus will take on a much lighter hue. H. Schridde (Virchow's Archiv, Vol. 175, No. 1) draws attention to certain islands in the esophagus which are rendered especially prominent by this method since they stain like the lining of the stomach. They were found in 70 per cent. of the cases examined and occur especially in the lateral folds of the upper portion. Microscopically branched tubular glands, lined with cylindrical epithelium, are found in these islands. The character of the cells and their nuclei, their power of secreting mucus and the occasional presence of border-cells give evidence of a close relation to the normal glandular structures in the lower portion of the esophagus and cardia. In two cases the areas were so large that they might have been regarded as small stomachs in the upper part of the esophagus. Probably these structures and the normal flat epithelium of the esophagus are genetically distinct; the former merely represent the remnants of the original lining which was not replaced by stratified epithelium as this began to proliferate downward. The islands were also sought for in a large number of mammals with negative result. A second article on the same subject is presented by A. Rückert who states that these glandular erosions are often wrongly diagnosed by pathologists as decubital ulcers. They are of importance in that they may give rise to an adenoma or a carcinoma and frequently lead to cyst-formation. They probably play no part in the development of diverticula, as some claim.

Elastic Tissue of the Spleen.—If studied with the Weigert stain, the spleen will be found especially rich in elastic fibers, but great care must be taken to properly differentiate the sections in alcohol, else structures such as the walls of the veins will also take the dye though only ordinary connective tissue. In studying the elastic tissue in pathological spleens, B. Fischer (Virchow's Archiv, Vol. 175, No. 1) finds that it may remain unaltered as in infarction or may simply stretch as in acute enlargement. In cir-

cumscribed inflammation such as in tuberculosis or abscess, a destruction goes on, and if the swelling is excessive (leucemia, amyloid degeneration) it may be difficult to find any elastic fibers. New formation goes hand in hand with proliferation of the ordinary connective tissue in chronic hyperplasia and also in shrinkage of the organ. Several varieties and degrees may be distinguished: (1) Compensatory new-formation. The relation of elastic fibers to the total organ here remains about normal. (2) Simple hyperplasia, where the percentage is above normal but the hypertrophy involves only parts which normally contain elastin. (3) Fibroelastic induration. Connective tissue and elastic capsule into the parenchyma. This is seen most frequently in syphilis. (4) Elastic hypertrophy of the capillaries. The capillaries are surrounded by dense sheaths of elastic fibers. Occasionally met with in the amyloid spleen, more often in leucemia. The different forms may be combined in various ways.

Experimental Pathology of the Liver.—By ligating the hepatic artery, R. Tischner (Virchow's Archiv, Vol. 175, No. 1) could bring out the development of necrotic foci throughout the liver due to thrombosis of the portal branches, increase of leucocytes and leucocytic capillary thrombosis, secondary to diminished vis a tergo. General connective tissue hyperplasia does not occur under these conditions; even hyperemia of the fibrous tissues is absent though local induration is seen in the larger infarcts and wherever the bile stagnates. The fat is increased within the necrotic areas but disappears toward the interior of the lobule. Similar necrotic foci also follow if the common duct is tied off; the cause here is the increased resistance offered to the flow of the blood in the portal system by the stagnation of bile. General connective tissue hyperplasia will begin in the periphery of the lobule and gradually spread toward its interior; circumscribed foci are, however, less common, since larger areas of necrosis occur only shortly before death. The fat behaves as above and the diminution in size of the organ is caused by its disappearance. Large doses of phosphorus administered rapidly will bring about sublobular necroses while the capillaries through the liver are filled with leucocytes. These changes and the increased and slowed flow of blood are best explained by a chemical irritation of the splanchnic nerve. Small doses continued over a long period are followed by hyperplasia of the liver cells and connective tissue, also induced by irritation of the vascular nerves, leading to slight hyperemia with acceleration of the blood-flow. If fatal, the pathological picture shortly before death will resemble that of acute intoxication.

PEDIATRICS.

Sudden Death during Infancy.—Nothing has a more depressing effect upon the physician than the sudden death of a child apparently in the best of health. An autopsy will generally explain the condition: either the child has died while vomiting or else it has been suffering from capillary bronchitis or toxic gastroenteritis. The part played by the thymus gland in causing compression of the trachea in rachitis, has been much overestimated, but undoubtedly many cases of glottic spasm are due to an acute swelling of this organ. In others death sets in rapidly with cyanosis, dyspnea and convulsions, and at autopsy nothing but a large thymus, not causing compression of any important organs, is found. Here the thymus is merely a symptom of a general lymphatic constitution and death is most probably due to cardiac failure in individuals possessing abnormally low powers of resistance. Such cases are of great medicolegal importance, since murder or, in individuals of more advanced age, suicide may be suspected; but the presence of a large thymus at autopsy will clear the case. Another form of sudden death, rarely mentioned by authors, is spoken of by E. Feer (Correspbl. f. Schw. Aerzt., Jan. 1, 1904); it is the eczema death in infants suffering from extensive skin eruption, eczematous in character. Its etiology is as yet unknown.

Exanthemata Following the Injection of Diphtheria Antitoxin.—This question is discussed by Oberwinter (Deut. med. Woch., Dec. 31, 1903), who describes several cases where an eruption followed the injection and was at first believed to be due to the antitoxin. Later developments showed, however, that they were cases of true scarlatina. He claims that an eruption which appears particularly from the third to the fifth day should always be viewed with suspicion, for he has found that in most cases it was genuine scarlet fever and probably due to a dual infection with both diseases. The fact that the eruption begins at the site of injection is apparently no proof of its being due to the serum, although the author does not deny that a true serum exanthem may assume the form of a scarlatinal eruption.

Pulmonary Complication of Measles.—Measles is generally a harmless disease, yet rightly feared on account of its pulmonary complications, when occurring in epidemic form, since the mortality then is apt to exceed 40 per cent. C. Hart (Deutsch. Arch. f. klin. Med., Vol. 79, Nos. 1 and 2) has had opportunity to study a large number of lungs at autopsy and finds that the appearance differs considerably from that of ordinary bronchopneumonia, for though typical areas of consolidation are unmistakable, the cut surface has a peculiar ragged appearance and dilated bronchi are abundant. The lower lobes were frequently consolidated in toto and the pleura often participated in the process, though not to a marked degree. The most important lesions are found in the walls of the bronchi which show epithelial desquamation, swelling of the submucosa, intense congestion and hyperactivity of the glands. Later on, the walls become infiltrated with round cells and the muscle and elastic fibers will gradually disappear so that dilatation can readily occur. The alveoli surrounding the bronchi will participate in the process and soon young connective tissue appears to replace the destroyed tissues. The contents of the alveoli varies considerably, but most often there is an intense desquamation of alveolar epithelium. If the process is especially severe, reactive suppuration does not occur and the bronchial walls with the adjacent parts of the lung undergo necrosis. The appearance of connective tissue forms an interesting feature, for it can often be noticed that young granulation tissue spreads into the lumen of the bronchi and alveoli wherever these are bared of epithelium, thus leading to an obliterating inflammation. Probably many cases of emphysema and chronic bronchitis in early life must be ascribed to a previous pneumonia secondary to measles.

Opotherapy in Kidney Disease.—A maceration of kidney substance in all diseases accompanied by urinary insufficiency is highly praised by M. J. Renaut (Bull. de l'Acad. de Med. de Paris, Dec. 22, 1903). The only disadvantage lies in the fact that maceration must be prepared fresh daily. These kidneys, preferably obtained from the hog, are freed from all attached tissue, minced and then digested for four hours with 450 c.cm. of saline solution. The decanted fluid is consumed by the patient in three or four doses during twenty-four hours. The albumin will decrease.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MARCH 5, 1904.

TYPHOID IN GERMANY.

Carlyle compared the advance of the world to the progress of some drunken man, who, reeling from one side of the street to the other, slowly and at the expense of much wasted effort finally arrives at his destination.

To one who is familiar with the history of medicine, even in its latest and most glorious period of development, this comparison must appear to possess a certain element of truth, touched, indeed, with the dyspeptic complexion of its author. There is scarcely a great acquisition of medical science regarding which opinion did not for some length of time oscillate between extremes, only eventually to reach and maintain the middle course of truth. And surely this is no disgrace. "To err is human," and, in view of this racial weakness, to weigh and test every opinion, and finally to reject the false and to retain the true, is the bright distinction of the scientific spirit.

Nevertheless, there are some opinions which even the most liberal are prone to regard as fixed and proven for all time. Such was the theory of the communicability of bovine tuberculosis, which had become established, apparently beyond the possibility of cavil, by the researches of Gerlach, Klebs, Chauveau, Bollinger, and others, in the early seventies of the last century. Yet Koch attempted, at a stroke, to sweep away the entire fabric as a cobweb. No less firmly imbued is the medical fraternity, whether clinicians or bacteriologists, with the conviction that typhoid, and especially typhoid epidemics, are due to infection through a contaminated water supply. And yet it would seem that this theory, also, has not the adamantine foundation with which it had been credited. In the February 20 and present issues of the Medical News are to be found a communication from a correspondent ("Typhoid Epidemiology"), wherein it is subjected to a criticism which might appear bold, were it not adequately sustained.

The writer, an American who had the good fortune to be engaged in the service of the German government as regular "Assistent" in a typhoid laboratory in Elsass, gained exceptional opportunities to study the development of the epidemics which were at that time prevalent. After a careful study of all the factors involved, he found himself driven to the conclusion that the water supply played no part in the dissemination of the epidemic, but that the infection was in each case communicated from man to man by personal contact.

The latter brings home an idea which is by no means new, inasmuch as it is now more than a year since Koch propounded the theory of "contact infection" in typhoid, but which is still somewhat foreign to Americans. The great German bacteriologist asserted that practically every case of typhoid was due to transference of infected material, either mediately or immediately, from the person of one victim to the mouth of the next. It appears, however, that the theory is not original even with Koch, but goes back far into the dim and ante-bacteriological days of medicine, since the clinicians of the earlier part of the century, among them Bretonneau and Trousseau held firmly to it. Be this as it may, it cannot be expected that the modern and deeply rooted theory will be abandoned without very convincing proofs as to its falsity. Admitted that the Elsass epidemic was traceable to a series of contact infections, as seems quite probable from the data so fully presented, it by no means follows that all other epidemics, many of which occur under vastly dissimilar conditions, are to be put in the same category. It may, indeed, prove to be true that "contact-infection" plays a far larger rôle in all epidemics than had hitherto been suspected; this is a question

which only a careful series of observations can adequately settle, but the evidence must first of all be thoroughly weighed and sifted. The question is one of such great importance to the race, that it behooves the medical world to make haste slowly—to creep, rather than stagger—like the drunkard of Carlyle, to the ultimate goal of truth.

THE PANAMA COMMISSION AND PROPHYLACTIC MEDICINE.

The Committee on Medical Legislation of the American Medical Association has indicated the keystone of the arch in the Panama Canal Commission. Surgeons, engineers, contractors, no matter how deserving of honor, nor how efficient in their work, will fall into what has long been called the "grave of the European" if they are not supported, nay more than that, controlled, by a medical officer who shall have full authority in carrying out the work of sanitation.

Our readers have but to refer to the article by George A. Soper, Ph.D., on Sanitary Aspects of the Panama and Nicaragua Canals, printed in the Medical News of January 4, 1902, to realize the importance of the request made by the American Medical Association, to President Roosevelt, that he appoint a representative of the medical profession upon the Commission.

Such work as was performed in Cuba by Dr. Walter Reed, can and must be done on the Isthmus if the work is to succeed.

The French failed for lack of man-power to put the excavations through. There were not enough natives to employ. The imported laborers from Jamaica fell sick and died, or gave up work in fear of death. The services of laboring men from the United States could not be counted on for three successive months, for before the end of the second month one-half of the force was on the sick list. In April and May of 1882, 37 engineers out of less than 100 died, and in September, 1884, it is said the Canal Company buried 654 officers and men.

There is no need that the new Panama Canal Commission should learn by personal experience the bitter lesson that the brave but fated French Company left behind it. Health, in what has been called the "Pest House of the Tropics," is the first essential to success. The mere presence of physicians and drugs will not ensure it; nothing but a rigid enforcement of sanitary laws under systematic authorized supervision will save to the Commission an adequate working force. The old French Company made the fatal mistake at first, of charging the contractors for the care of men in the hospitals, which policy kept many men at work when they should have been under medical care.

With this record of the first Panama Company's inefficient struggle against the fevers, dysenteries and depressing effects of the climate of the Isthmus it is a relief to turn to the contribution to the Medical News, made in the issue of April 12, 1902, by Henry L. Abbott, Brevet Brigadier General U.S.A. (Retired). He translated the statistical report presented by Dr. Lacroisade, the Medical Director of the new Panama Canal Company, in which it is shown that the percentage of disease and mortality among the new Company's employees was reduced in 1901 to about one-third of what it had been in 1881.

The message of Dr. Soper, after his residence in Panama was emphatic. A department of health, such as established by the Suez Canal enterprise, must be established in the Isthmus, with more than usual power of enforcing sanitary laws. The work of this organization must be not merely critical, it must be an active constructive organization. "It should," he says, "include the procuring and protecting of pure water supplies, and the prompt and permanent disposition of the daily wastes which will occur among the thousands of laborers who will be gathered together in camps and settlements." Hospitals along the line of work must be established, medical inspectors must examine the laborers to detect the presence of illness. Hours of work must be regulated, habits controlled, diet and housing overseen by the department of health, and the contractors must submit to a military-like enforcement of labor rules, such as is wholly unknown in our equable climate if they would keep their officers and laborers in working condition.

But the health of the employees as a means to the triumphant achievement of the Panama Canal is not the chief reason why medical men so strongly urge the President to appoint a medical officer on the Commission; it is the health conditions that are likely to occur when the canal is completed, that are the most serious menace to the country.

The short cut for commerce offers just as short a cut to disease. The cholera from Hongkong, Calcutta and Bombay, the plague from China and India, the fevers of South America will all converge to those narrow waters, and will be communicated by sailors who will want to spend a few hours on shore and catch up with their vessel

by train. Only the most rigid inspection and well-established quarantine stations will prevent the canal from becoming a focus of disease. Once let plague, cholera and yellow fever get a footing among the population that will settle along the completed canal, and instead of being a boon to commerce the waterway will become a curse; for no matter if a ship comes from a clean port, she would not be admitted by the quarantine officers of any healthy city, if she had just spent a day and a half in an infected country.

We consider that it is of the utmost importance as an economic measure that a medical man should be numbered among the members of the Commission and that detailed preparations should be begun at once, in harmony with engineering projects, so that the builders may begin their work with an efficient sanitary and medical organization.

It is noted that Col. W. C. Gorgas, of the U. S. Army and its expert in tropical diseases, has been called in consultation with the members of the Commission and will in some measure have charge of these sanitary problems. They could be entrusted to no better hands. However, if the President rises to a full appreciation of the economic importance of health in its bearing upon the success of this prodigious undertaking, both during its construction and thereafter, he will not hesitate to clothe Col. Gorgas with the dignity and authority of a full member of the Commission.

AUTOPSIES IN PUBLIC HOSPITALS.

Assembly Bill No. 227, recently introduced into the legislature by the Hon. W. Y. Robinson, at the request of the Superintendent of the Craig Colony for Epileptics is "An Act to Amend the State Charities Law in Relation to Autopsies at the Craig Colony for Epileptics," and is as follows:

"Section XI. Have power (the Superintendent), subject to the supervision and control of the Board of Managers, in case of the death of any patient at such institution, who shall have been maintained therein wholly at the public expense, to make, or cause to be made, an autopsy on the body of such patient."

There is every reason, in our opinion, why this Bill should become a law. Germany is admittedly the leader to-day in scientific medical research. This is largely due to the fact that autopsies are permitted on the bodies of all patients who die in the public hospitals. Artificial and sentimental objections should no longer be permitted to stand in the way of scientific investigations, carried on for the benefit of the entire human race. There is a vast amount of valuable material at the Craig Colony that ought to be freely at the pathologist's disposal.

This Bill is unquestionably a step in the right direction. We hope it will pass and receive executive approval, and that the time is not far distant when a similar general law applicable to all public institutions in the State may be enacted.

A NOVEL ASPECT OF THE ALCOHOL PROBLEM.

The laborious investigations and the animated controversies on the physiologic, therapeutic and economic phases of the alcohol question, must, temporarily at least, surrender the stage to an aspect that has but recently presented itself to the speculative mind. In the concluding remarks of his report on alcohol treated from the standpoint of the chemist, in the "Report of the Committee of Fifty," Prof. Abel, of Johns Hopkins University, although strongly emphasizing the effects of alcohol as a highly toxic agent, finds it impossible to advocate the doctrine of total abstinence, on the ground that those who have not the physical or moral power to resist a tendency to excess, will in the long run be eliminated from the race for existence; in this way there would be evolved a human species possessing a higher degree of stability and invulnerability than at present. The same view has been recently echoed by Dr. Woods Hutchinson, before the Oregon State Conference of Charities and Correction, who extols alcohol as a virtue, as a powerful factor for the elimination of the unfit from society.

This ingenious application of the doctrine of evolution arouses the close attention of the sociologist no less than that of the biologist and clinician. A safe working hypothesis in solving many a scientific riddle, natural selection would seem in this instance to add another triumph to its list. Close analysis, however, reveals that here the principle of natural selection is misapplied.

There can be no doubt that alcohol has shattered the hopes and destroyed the lives of thousands and that it has succeeded in accomplishing this because it has encountered individuals enfeebled by the hereditary influences of psychical degeneration and by the physical and mental stresses of civilization. Bearing the mask of a kindly friend, a power to allay pain, relieve misery and produce the sensation of physical well-being, alcohol has, to be sure, acquitted itself as a skillful executioner, alluring its victims to gradual dissolution and branding the marks of degeneration upon their descendants.

This theory presupposes that he who falls prey to the fell hand of alcoholism is himself the bearer of the birthmark of degeneration. That this is true in a large proportion of cases cannot be questioned. Yet is it not a common experience that lives that have given promise of a healthy physical and mental development, have frequently succumbed to its insidious influences? Certain adverse circumstances of temporary illness, distress or pain, rather than hereditary influences, have in not a few instances been the determinating factors of many a case of morphinism and the like. This is probably no less true of alcoholism. Not only is this condition not solely dependent on degeneration for its production, but it is also one of the most potent influences that make for degeneration.

Instead of being hailed as an instrument with which nature threshes out the unfit from society, alcohol should rather be credited with but a limited sphere of influence in this connection. Its operations are far from being universal. Who would venture to assert that all degenerates are alcoholics, that all those whose numbers swell the ranks of the insane and the criminal classes are addicted to alcohol? To be sure, this treacherous drug is one of the chief causes of insanity and crime, yet the very fact that criminals and the insane are not always such because they have been alcoholics, proves the imperfection of this agent as a universal factor of elimination.

If nature requires toxic and pathologic agents as aids in the furtherance of her cosmic design, is it necessary to single out alcohol when tuberculosis decimates the ranks of the physically unfit and when a host of other infections lie in wait for those who come into the world with but a meager inheritance of resistive vitality? If it be admitted that these also are in the long run beneficial to the evolution of a better race, as is claimed for alcohol, then the art of medicine will no longer have any excuse for existence and treatment will be unjustifiable. One is here brought face to face with the same thought that presented itself to Huxley and Spencer, namely, that it is impossible to reconcile the processes of evolution with the aims of ethics. The conclusion is inevitable that alcoholism should be placed in the same category with other diseases as insidious foes of humanity, and it is in the interest of society to seek the real significance of the various factors such as predisposition, environment, climate and contagium, that lie at the basis of all of them, with the object of their extinction.

ECHOES AND NEWS.

NEW YORK.

Dr. Peterson Resigns.—Dr. Frederick Peterson has sent to Gov. Odell his resignation as a member of the State Commission in Lunacy. Dr. Peterson is President of the board and states that the duties of the position interfered with his private practice.

Clinical Assistants at Gouverneur.—The Trustees have appointed Dr. Stella Stevens Bradford and Dr. N. Gilbert Seymour Clinical Assistants to the Tuberculosis Clinic, Out-Patient Department of Gouverneur Hospital.

Opening of Medical Club Rooms.—The library and club rooms of the Eastern Medical Society in Clinton Hall, 151-153 Clinton Street, near Grand, were opened on Tuesday evening at 8 o'clock. Addresses were delivered by Dr. Abraham Jacobi, former Judge Julius M. Mayer, Dr. Kenneth M. Milliken, and Dr Joseph D. Bryant. A concert and supper followed.

Ratification of Unification Plans.—Up to March 1, the following County Societies in New York State have ratified the Joint Resolution of the State Society and State Association, Albany, Cayuga, Chemung, Dutchess, Franklin, Kings, Monroe, Oneida, Onondaga, Ontario, Rensselaer, Schenectady, Broome and New York.

Odell's Care of the Insane.—According to the *Sun*, "the 'business' Governor's unbusinesslike administration of the affairs of the State insane hospitals has culminated in the resignation of Dr. Frederick Peterson of New York City from the office of President of the State Commission in Lunacy. This, of course, is but the logical outcome of the Governor's methods of dealing with the insane in this State. The memorandum filed by the Governor when he approved the bill abolishing the boards of managers of the hospitals for the insane and centralizing the management in the hands of the State Commission in Lunacy at Albany, purported to give the reasons for such approval, but it bore on its face the readily distinguishable earmarks of the Hon. Goodwin Brown, a former legal member of the State Commission in Lunacy, who is reputed to have prepared it at the 'business' Governor's behest. Mr. Brown, it may be recalled, failed of reappointment at the end of his term as State Commissioner in Lunacy, although many powerful wires were worked in his behalf, because Gov. Roosevelt, to a considerable extent guided by the advice of the State Charities Aid Association, concluded that a change would not be prejudicial to the public interests. So William Church Osborne was appointed in Mr. Brown's place. In this memorandum the Governor says:

"'No department of government should have more earnest consideration than this which controls a population of over 23,000,' and in his arguments in behalf of the measure he said it was much better to take the power away from the boards of volunteer managers and to place it in the hands of men who could give all their time to the work. This is what the Governor said to the public. But his arrangement with the president of the Lunacy Commission was that he need give only two days a week to this work deserving such 'earnest consideration,' which includes the care of 25,000 insane people and an annual expenditure of approximating $5,000,000. So Dr. Peterson took the place, continued to attend to his extensive private practice in the city of New York and to devote a fraction of his time only to the duties of his great office. Last winter the legislature was obliged to authorize the State Commission in Lunacy to employ a medical inspector at $3,500 a year to relieve the president of the commission of a considerable portion of his work and responsibilities.

When Commissioner Osborne, the legal member of the Lunacy Commission, resigned his office because of disgust with Odellism in connection with the State hospitals and charities, Gov. Odell appointed the Hon. Daniel Lockwood of Buffalo to the vacant place. Commissioner Lockwood has a substantial law practice in Erie county, and he has been able to devote only a portion of his time to the affairs of the commission. With the 'medical' member and the 'legal' member of the Lunacy Commission giving so much time to their private business much of the work necessarily devolved upon the 'business' member of the commission, the Hon. William L. Parkhurst, of Canandaigua. Commissioner Parkhurst has doubtless done the best he could under the circumstances, with the advice and assistance of his fellow townsman, the Hon. John Raines, for whose entrance into politics Commissioner Parkhurst has said to have stood sponsor. But Commissioner Parkhurst, who really knew nothing about the insane until after he took office, is not as young as he once was, and for some time has not been in the best of health, so that the clerks in the lunacy department have had to run things to a considerable extent. Thus, despite the patching and other repairs, this beautiful machine designed by the Governor, with the advice and assistance of the Hon. Goodwin Brown, to give 'earnest consideration' to the care of the insane, has broken down to such an extent that important changes are urgently needed. As Commissioner Lockwood's term expires next December, it is said that the Governor during the present session will name the Hon. Goodwin Brown to succeed him. Then, with Commissioners Parkhurst and Brown as a majority of the Lunacy Commission, the Governor will have fully realized the political results flowing from his policy of centralization, and the medical member of the commission, no matter how reputable he may be, would be a nonentity so far as the administration of the affairs of the Commission in Lunacy would be concerned. Meanwhile it is pertinent to ask how the insane have fared under this system of neglect, with its large promise but lame performance. It is true that in the name of 'economy' they have been deprived of proper food, that they have been housed in three-story, non-fireproof structures, where formerly two-story buildings were used, and that the recovery rate shows a marked decrease. But who can ever know or tell the total amount of hardships and sorrow resulting from the change in management in the insane hospitals, so strenuously insisted upon by Gov. Odell?"

In Honor of Dr. D. B. St. John Roosa.—A number of distinguished men of this and other cities, including the foremost members of the medical profession, and of those prominent in literature, the law, finance, and the commercial world, gave a dinner in honor of Dr. D. B. St. John Roosa, "and to commemorate the twenty-one years since the inauguration of post-graduate medical instruction in this country," at Delmonico's, last Tuesday evening, March 1. Dr. William Osler, of Baltimore, presided at the dinner, which was given by the following gentlemen: William T. Bull, M.D.; Francis Delafield, M.D.; Bache Emmet, M.D.; Virgil P. Gibney, M.D.; Edward G. Janeway, M.D.; Wm. M. Polk, M.D.; A. A. Smith, M.D.; A. H. Smith, M.D.; Robert F. Weir, M.D.; Albert Vander Veer, M.D., Albany; A. W. Calhoun, M.D., Atlanta, Ga.; W. H. Welch, M.D., Baltimore; W. S. Halsted, M.D., Baltimore; C. I. Blake, M.D., Boston; M. H. Richardson, M.D., Boston; W. W. Keen, M.D., Philadelphia; J. H. Musser, M.D., Philadelphia; J. C. Wilson, M.D., Philadelphia; G. B. Johnston, M.D., Richmond; W. J. Mayo, M.D., Rochester, Minn.; James W. Alexander, Edward T. Bartlett, Cornelius N. Bliss, William D. Howells, Morris K. Jesup, Edward King, John E. Parsons, J. Edward Simmons, J. H. Van Amringe.

Dr. Roosa has been president of the Post-Graduate Medical School since its establishment in 1882. There were eight physicians of this city in the decisive movement which brought about the establishment of the Post-Graduate Medical School. Dr. Roosa is the only one of the eight still connected with the institution. The seven others were Dr. William A. Hammond, afterward surgeon-general; Dr. James L. Little, Dr. Frederick R. Sturgis, Dr. M. A. Pallen, Dr. Stephen Smith, Dr. Henry G. Piffard, and Dr. J. W. S. Gouley. They were from 1875 to 1882 the post-graduate medical faculty of the University of the City of New York. As such they were working under marked disadvantages, which they realized completely, but were unable to overcome. This was what caused the failure of the movement. For a long time the faculty sought to bring about an improvement of conditions, the separation of post-graduate pupils from those not yet graduated, the proper distinction between first-year men and those of the second year, and between these and third-year men, and the upshot of it was that on April 4, 1882, the eight members of the faculty resigned. The resignations were accepted. Thus the Post-Graduate Medical School was born, the eight secessionists renting rooms in the old College of Pharmacy in Twenty-third Street, between Second and Third avenues, and going on with their work as if nothing had happened. For a year and a half they remained in Twenty-third Street, and then went into Twentieth Street, first renting and then buying the property now occupied by the Columbus Hospital at No. 226 East Twentieth Street. The next move was the erection, five years ago, of the fine structure at Twentieth Street and Second Avenue, which is a hospital with 207 beds, as well as a school for post-graduate instruction. Of the advantages of post-graduate courses, Dr. Roosa said: "Post-graduate medical instruction is an essential. The more thorough a man's training in his medical school has been, the more valuable to him is a post-graduate course. The character of the instruction in the Post-Graduate Medical School is similar to that given in such institutions in Berlin and Vienna, save that we have amplified it; in fact, in Prussia they imitate us now. We have between 600 and 700 pupils yearly, many from Canada, and occasionally one from Europe. Most of the pupils have been engaged in the practice of medicine, because when a physician or surgeon finds, for instance, that the demands of his practice are very great, say, by way of example, in a matter of surgery, he can come to this city, enter a post-graduate class, and make a most careful, exhaustive study of the particular surgical question. He can perform a desired operation two or three times upon the dead; he can assist when it is performed upon the living, and thus gain reliance and skill to enable him to perform it himself. We teach physicians how to do things. In their undergraduate work they watch their preceptors perform operations; in our work they perform the operations under the guidance of their preceptors. Also we teach laboratory work very thoroughly. This has become such an important factor in the medical science of the day that we devote a great deal of attention to it, for by its agency the medical profession has been able to determine many things of which, in former years, it knew but little. So, in order that a physician or surgeon may be able to do good work he must take a post-graduate course. New York's work in the direction has been followed by the establishment of post-graduate schools in Philadelphia and Chicago, and other cities. In my early days there was no such thing as post-graduate instruction in this

country, and in 1863 I had to go to Berlin and Vienna for a post-graduate course."

Dinner to Dr. M. Nitze.—On March 9 will be the twenty-fifth anniversary of the first demonstration of the cystoscope by Prof. Max Nitze. A committee consisting of Prof. Carl Posner, Dr. Hans R. Wossidlo and Dr. H. Goldschmidt of Berlin, has been charged to arrange a celebration of the occasion. A part thereof will be the presentation of an address, to which it is proposed to attach the signatures of those who have a general or special interest in genito-urinary diseases. The undersigned is authorized to obtain the signatures of those American colleagues who may desire to be thus represented in the address. As it will be impossible to obtain the signatures in time to reproduce them on the address, the committee suggests that a congratulatory cablegram precede them. The following cablegram is therefore submitted, to be cabled on March 9: "Professor Max Nitze, Berlin: Your colleagues and pupils congratulate themselves and the profession on the twenty-fifth anniversary of the demonstration of the cystoscope. Vivat Magister!" To be followed by the names of those who desire to have this done. The wording of the above cablegram will be changed in accord with such suggestions as may be made. Physicians desiring to have their names signed to the cablegram should address the undersigned. In such an event calculate 25 cents for each word of signature and address. F. Valentine, 31 West Sixty-first Street, New York.

PHILADELPHIA.

Fire in Dental College.—A fire which originated in an anatomical room of the Pennsylvania Dental College on February 24, damaged the building and contents to the extent of $5,000. The 150 students and 30 patients who were in the building at the time succeeded in getting out safely. The loss was confined mainly to anatomical specimens, preparations, and charts.

Wood Alcohol Found in Whisky.—The discovery that wood alcohol is largely used for the adulteration of whisky in Philadelphia and vicinity has been made by the State Dairy and Food Commissioner. Prosecutions against dealers in the country districts have begun and others are to follow. Analyses show that more than 60 per cent. of the samples obtained by the agents contain a dangerous percentage of the adulterant.

Local Nurses Will Go to Japan.—It is stated that at a recent meeting of the local Red Cross Society it was decided to send ten trained nurses from this city to care for the wounded soldiers of Japan. A fund of $5,000 must first be raised to fully equip the nurses for service. They are to be under the charge of Dr. Anita McGee, of Washington, D. C., but the whole management of the enterprise is to be assumed by the society of this city which is not in affiliation with the National Red Cross Society. Only nurses with Spanish-American war experience will be eligible.

State Tuberculosis Commission Organizes.—The commission appointed by the Governor to assist the State Live Stock Sanitary Board in formulating rules for the guidance of meat inspectors met at Harrisburg, February 26. Organization was effected by the election of Governor Pennypacker as President; Drs. C. B. Penrose and C. Y. White, both of Philadelphia, as Vice-President and Secretary, respectively. Sections were formed to report at a future meeting on the relation of bovine to human tuberculosis; foreign methods of dealing with tuberculous cattle; the pathology of bovine tuberculosis, and methods of disposing of tuberculous meat and cattle in Pennsylvania. The next meeting will be held in April.

Railroad Hospital Cars.—Four hospital cars of special design are to be built for the Pennsylvania Railroad. They will contain a morgue, operating room, beds for the injured, supplies and quarters for physicians, nurses and attendants. The cars will be kept at the division terminals of Philadelphia, Harrisburg, Altoona, and Pittsburg and will be in readiness day or night to furnish prompt relief at wrecks.

Report on the Butler Epidemic.—At the meeting of the State Board of Health held February 27, a report on the recent typhoid epidemic at Butler was made and adopted. As a result of the epidemic, 105 persons lost their lives. The report contained the following recommendations: (1) The absolute necessity for the prompt reporting of every case of typhoid fever to the Health Department; (2) at least weekly bacteriological tests of the water supply, and the monthly patrolling by health officers of the watersheds of the State; (3) the insistence on the part of the health authorities that all water be boiled before being used in a community, when an unusual number of cases of typhoid develop; (4) the slow sand filtration of all water, as this system of filtration will intercept typhoid fever germs. The report was approved and 5,000 copies ordered to be distributed throughout the State.

CHICAGO.

St. Elizabeth's Hospital Report.—A report of the work done at this hospital during the last year has been issued. It shows that 2,240 patients were treated, no remuneration having been received in 411 cases.

Requests of Health Commissioner Reynolds Denied.—The Finance Committee of the City Council has denied the requests of Health Commissioner Reynolds for increases of $15,000 for vaccination expenses; $10,000 for antitoxin; $32,000 for more sanitary inspectors, and $2,500 for more tenement house inspectors.

Original Research Regarding Human Perspiration.—In a paper on this subject, Dr. Julius H. Hoelscher, of this city, details reports of experiments on the human perspiration under the influence of drugs and in certain pathologic conditions. After a thorough cleansing, he enveloped his subjects in sterile gauze and over this secured an oil cloth. The subject was then subjected to dry heat, not over 120° F., for one to two hours. When the point of tolerance had been reached, the soaked gauze was quickly removed, submitted to pressure, and the sweat collected, the amounts ranging from three to thirty-two ounces. He offers the following deductions from the experiments conducted: (1) The hot air causes an aseptic fever or temperature elevation, despite the antipyretic action of acetanilid, sodium salicylate and quinine. (2) The hot air bath is of decided value in acute and chronic uremia, shown by the fact that the perspiration contains a considerable excess of urea and nitrogen. (3) In articular rheumatism in conjunction with salicylates, the hot air bath gives more rapid results and lessens cinchonism. (4) Certain types of myocarditis seem to be benefited by the hot air bath, and he reports a case. (5) Pilocarpine should never be used without the aid of hot air applications to the body. So combined, there is no sialagogue and less toxic drug effect, and far more sweating than otherwise. (6) Three cases of

catarrhal jaundice were sweated; all the tests failed to show bile pigments, only the epithelial debris containing bile deposits. (7) Modern sugar tests failed to reveal sugar in the sweat from diabetics. (8) A case of chronic constipation and indicanuria did not disclose the presence of indol or skatol in the sweat. (9) As regards the function of eliminating normal and abnormal substances, the skin is not to be compared with the kidneys. (10) Free sweating seems to favorably affect psoriasis, though further study is required, as also the effect on other skin diseases. Lastly, 1,000 c.c. of sweat contains about 11.5 gm. of solids (nearly 3 drams), one-half inorganic and one-half organic, and about .6 gm. (9 grains) of urea and .47 gm. (8 grains) of nitrogen.

The Use of the Cystoscope in Catheterizing the Ureters as a Means of Diagnosis in Surgical Diseases of the Kidneys.—Dr. Louis E. Schmidt read a paper on this subject before a recent meeting of the Chicago Medical Society. He stated that examination of the bladder, catheterization of the ureters, examinations of the functional activity of the kidneys by examining separately the collected urines, especially with the aid of cryoscopy and radiography give almost certain information by which one may be safely guided in this field of operative work. As to cystoscopy, every diagnostician agrees as to its true value in this work. With the help of the cystoscope the presence of only one or of two ureteral openings can be determined, and whether or not clear, turbid, blood-tinged, or colored urine is being secreted from one or both sides. The appearance of the ureteral orifices, torn after the passage of stone, as reported by Halban, inflammatory signs of the mucosa, or tuberculous processes, papillomatous growths about the urethral orifice may designate descending processes. After inbibition per mouth of methylene blue, the urine becomes tinged green in from fifteen to thirteen minutes in the case of a normally secreting kidney. The greater the amount of parenchyma destroyed, the longer the time which elapses previous to the appearance of the tinged urine. Voelcker and Joseph have injected 16 centigrams of indigo-carmine into the gluteal muscles. It begins to make its appearance in the urine in from fifteen to thirty minutes. It has the advantage of being excreted solely by the kidneys, and is harmless. The same authors gave individuals iodide of potassium and filled the bladder with a solution of peroxide of hydrogen containing starch. As soon as the iodide of potassium was being excreted, the urinary whirl became of a bluish color. Where catheterization of the ureters or segregation is impossible or undesirable, where the ureteral openings cannot be seen, it is possible by means of a cystoscopic examination to make some deductions as to the functional activity of the kidneys when considering the foregoing points. Besides, it is possible to ascertain approximately the functional activity by watching the frequency and force of each contraction, the quantity of urine which is expelled at each contraction of the ureter, and also some idea as to the ascent or descent of the whirl when the bladder is filled with fluids of varying specific gravities. Reference was made to the use of the different segregators. After considering the advantages and disadvantages of the various methods, the author said that ureteral catheterization is constantly becoming more popular. While he does not care to make a comparison of segregation and catheterization of the ureters, he believes there are but few, if any, authentic cases of infection of the ureter following catheterization. There can be no question in the minds of those who have followed the subject, and who have had practical experience, that the establishment of the functional activity by the examination of the urine gained by ureteral catheterization is the most important achievement in renal surgery. In addition, certain information which is of importance in every case is derived by ureteral catheterization, which any one of the segregators and cystoscopy alone cannot give. It is a method of diagnosis which can give valuable information in both ureteral and renal affections. Where a stone in the ureter has been diagnosed and the skiagraph shows it to be correct, Kolischer, Caspar, Hausmann, and the author have been able to inject sterilized liquid vaseline, which has been sufficient to cause contractions and to loosen the stone and cause the spontaneous expulsion of it into the bladder, and then subsequently to be passed naturally per urethram. It is not to be forgotten that when a catheter or bougie is in place, it can be used as a guide in ureterotomy, and also to locate and prevent traumatism of the ureter whenever bound down by tumors or inflammatory processes. Whenever performing a plastic or other operation, on the pelvis or kidneys, a bougie in place may serve as a guide. For draining the pelvis in cases of pyelitis and flushing it out and treating it, nitrate of silver, or other solutions have long been in vogue, and in some cases with positive results.

GENERAL.

Cars for the Tuberculous.—Consumptives may be barred from first-class Pullman cars on the Santa Fé Railway. The plan involves the running of hospital cars at intervals on through trains. These cars will be specially equipped, and no one except sick persons will be allowed to ride in them. This innovation in train operation will be put into effect between Chicago and Kansas City to Colorado and New Mexico health resorts, and to California points, over practically the entire system. The care of consumptives has always been a burden to the railroads. After a berth has been occupied by a consumptive, it must remain unoccupied until the end of the run, when it is disinfected. This precaution for the care of health of the traveling public involves expense.

Dr. Gorgas for Canal Commissioner.—The Committee on Medical Legislation of the American Medical Association has asked the President to appoint on the Panama Canal Commission a representative of the medical profession, and has recommended Col. William C. Gorgas, a surgeon in the army, for the place. It is urged that "under both of the French administrations at the Isthmus the engineering problems themselves, to the chagrin of the medical profession of the world, failed of accomplishment largely through the frightful mortality among officers and laborers consequent upon lack of authority on the part of medical officers entrusted with the work of sanitation; that the same conditions of insalubrity exist now that existed then, and that consequently the sanitary problems are to be recognized as second in importance, if second at all, only to those connected with the engineering department."

Prof. Loeb's Studies in Infection and Immunity.—Dr. Jacques Loeb of the University of California has thrown some light upon the problem of infection and immunity from disease in recent experiments made in the fertilization of the egg of the sea-urchin with the sperm of various species of star-

fish and holothurian. The key to Dr. Loeb's hypothesis is found in the fact that fertilization in different cases has been found to depend upon slight variations in the constituents of the sea water used. Arguing from this, Dr. Loeb says there is reason to believe that the predisposition to infection in the human body may depend on equally slight variations in the constitution of the liquids of the body. The presumption, then, is that when the right variations are found and the manner of producing these safely and surely is determined, science's great battle against disease will be near an end. It is reported that taking the eggs of the sea urchin, Dr. Loeb, in his laboratory at Berkeley, has been able to fertilize them with the sperm of such species of starfish as the asterias, the brittle-stars, and the twenty-ray starfish; also with the sperm of the *Holothurian cucumaria*. Hybridization of different species was sometimes possible under these conditions, and sometimes impossible. The addition of a small amount of sodium carbonate to sea water made a new series of differences, all of which have the great est significance. Dr. Loeb generalizes from this fact as follows: "The fact that the possibility of fertilization depends on the presence or absence in the surrounding solution of mere traces or very minute quantities of certain substances gives rise to the idea that the main variable determining the entrance of the spermatozoon into the egg may be of the nature of surface tension or a function of the latter. This idea would also harmonize with the fact that there are great individual variations in the sperm of the starfish of the same species in its power of fertilizing the egg of the sea urchin. These facts may have some bearing on the problem of infection and immunity. Especially that which we call the predisposition for an infection may depend on equally slight variations in the constitution of the liquids of our body as the variations on which the fertilization of the sea urchin eggs with the sperm of the star-fish in sea water depend. If our supposition be correct that in the latter case the controlling variable is of the nature of surface tension, it stands to reason that the variable in the case of the individual predisposition for infection is also of this nature."

Proposed Army Medical Reserve Corps.—"The position of contract surgeon in the army is sought to be abolished by a bill introduced by Senator Proctor on the recommendation of Surgeon-General O'Reilly," says the *Evening Post*. "The army employs at present about 200 contract surgeons, who are civilians, and cost the Government more than would an equal number of young commissioned officers. This does not include the physicians who are occasionally called in for short periods for such services as the physical examination of men at recruiting stations. The position of contract surgeons is anomalous in many ways. Irrespective of their professional skill the common soldiers do not regard these men in the same way as the regular army surgeons. They are not treated as officers, and, though they wear a uniform, it bears no insignia of rank. In place of the body of contract surgeons, Senator Proctor's bill creates a 'medical reserve corps.' The President is authorized to issue commissions as first lieutenants in this corps to graduates of reputable schools of medicine, who are properly qualified. Contract surgeons now in the military service, if recommended by the surgeon-general, are eligible without further examination. The holder of a commission in the medical reserve corps is to have the authority, rights and privileges of a commissioned officer of the same grade in the regular medical corps, except as regards promotions, during the time he is actually called into active duty. The pay and allowances of first lieutenants of the medical corps shall be given to them for the same period. The system is made flexible by a clause providing that no officer of the medical reserve corps shall be ordered into active duty, if he is unwilling to accept such service, and by another clause which permits such officers to serve with the militia or volunteers, or in any other capacity under the national Government. The cost of the change, according to the surgeon-general's estimate, would at first be no greater than under the present system, though at the end of four years it will cost some $50,000 more. The problem of supplying medical service to the army is in many ways a peculiar one. A civilian surgeon may be perfectly competent to attend to wounds in a hospital and look after such purely professional duties, but his experience does not fit him for the administrative part of his work—the organization of field hospitals, the transportation of the wounded, and such purely military matters. Even for such work as examining recruits, civilian physicians are not always equipped. Many, of course, have served as life insurance examiners, but the point of view of that work is different. The insurance company wants to insure the applicant if this can be done with but little hazard, while the Government does not want to take any chances whatever with a recruit. Defects, often, which impair a man for military service do not shorten his life. Thus in many ways it is of great value to have on call a body of men who are somewhat experienced in the particular kind of work that they may be required to do for the men of the army."

Tenth International Congress of Ophthalmology.—The Committee of the Tenth International Congress of Ophthalmology has authorized Prof. Dr. A. Siegrist, of Bern, Director of the Ophthalmological Clinic of the University, Bern, with the preparations for the appropriate exhibition of all scientific apparatus, instruments, and the various appliances for instruction, which will be sent to the Congress. He therefore requests all colleagues, as well as all scientific, optical and mechanical firms who wish to exhibit any objects at the International Ophthalmological Congress in Lucerne to apply to him before July 1, 1904, giving an exact statement of the object to be exhibited, of the space demanded, and of the kind and strength of electric force which may be required. Objects which are announced later can only be accepted as far as the space at disposal will still allow.

First French Congress of Climatotherapy and Hygiene of Towns.—As has already been announced, this Congress will be held at Nice, April 4 to 9, under the presidence of Professor Chantemesse, of Paris, member of the Academy of Medicine. The members of the Congress will be allowed reductions (50 o/o and upward), the greater part available from April 1 to 20, 1904, on the great railway lines of France, the south of France and Corsica; on certain English railways (London to Paris) on the steam liners, running between Nice, Marseilles, Corsica, Genoa; on the Italian railways; on sleeping-cars in France and abroad. Reduced prices have already been conceded at the chief hotels in Nice, Beaulieu s/m, Cannes, Mentone, Monaco, etc., a list of which will be supplied, on application to Dr. Camous, 2 rue de l'Opéra, Nice, specially charged with this matter. Outside of Nice, the members of

the Congress will officially visit Monaco, Mentone, Cannes and Grasse, where fêtes and excursions will be organized in their honor. His Serene Highness, the Prince of Monaco, will hold a reception at the palace, and there will be a gala representation at the casino. At Nice, besides the reception by the authorities, there will be gala representations (opera, etc.). The number of places, limited in the theaters, will be reserved to the first booked. After the close of the Congress, excursions will be organized. Medical students, the families of the members, accompanying the latter, and adhering to the Congress (special ticket, 10 frs.), will enjoy the same advantages. In order to take part in the Congress, it suffices to remit to Dr. Bonnal, Treasurer, 19 boulevard Victor Hugo, Nice, the amount of the subscription (20 francs), together with names, qualities, titles, exact address very legibly written, and accompanied with the subscriber's visiting card. Members desirous of making any communication are requested to send the title and summary of it (30 lines in 8vo) to the Secretary-General before February 20, so that they may be published and distributed before the meeting of the Congress. For further information, apply to Dr. Hérard de Bessé, General Secretary, Beaulieu s/m, Alp.-Marit.

OBITUARY.

Dr. Ogden Ludlow, of New York, died last Wednesday of typhoid fever.

Dr. R. J. Wilding, of Malone, N. Y., Secretary of the State Medical Society, died suddenly Wednesday night of heart disease, aged sixty-seven years.

Dr. David D. Toal died on Friday last. He lived at 151 Avenue B and was known to nearly every man, woman and child in the region. Dr. Toal was born in Ireland 66 years ago. His parents brought him here when he was two years old. They were poor, and he managed to educate himself by working in a shop and studying nights. He was graduated from the University Medical College in 1867, and began practice in East Eleventh Street.

Dr. Emory Potter, the leading Prohibitionist in Saratoga County and chairman of the county committee, died suddenly of heart failure at his Elmwood Hall home on Saturday night. He was stricken with pneumonia on Tuesday last. He was a native of Union Valley, Cortland County, N. Y., and made Saratoga Springs his permanent home twenty-seven years ago.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, February 13.

THE MEDICAL EXAMINATIONS OF THE UNIVERSITY OF OXFORD—PROPOSED SAFEGUARD AGAINST LIVE BURIAL—LONDON SCHOOL OF MEDICINE FOR WOMEN.

In a previous letter mention was made of Sir John Burdon-Sanderson's resignation of the Regius Professorship of Medicine at Oxford, and of the fight for the vacant chair that followed thereupon. The teachers of the Faculty are anxious that the Chair of Medicine should be converted into one of Pathology, which they wish to see filled by Dr. James Ritchie, at present Reader in that subject. The medical graduates of Oxford, of whom there is a considerable body in London, are strenuously resisting this proposal, on the ground that a man is wanted who has a practical knowledge of the requirements of the medical practitioner and of the details of qualifying examinations in accordance with the standard approved by the General Medical Council. The true inwardness of the situation is that a year and a half ago the clinical parts of the Oxford Final Examination for the degrees of Bachelor of Medicine and Surgery were pronounced to be seriously deficient by the Visitors of the Council. The Oxford men naturally resented this criticism, but could not wholly deny its justice. They laid the blame for the shortcomings of the examination, however, on Sir John Burdon-Sanderson, who, it was alleged, had neglected his duty. Sanderson, it should be stated, is devoted to pure science. He walks through life, striking the stars with lofty head, as Horace says, and taking no heed of the practical applications of scientific truths. He is absent-minded and forgetful of things which he looks upon as trifles, and those who know him best are most ready to believe that, with the highest aspirations and the noblest motives, he has failed to bring his mind down to earth in the matter of examinations in terrestial matters like medicine, surgery and obstetrics. Such "bread studies" do not interest him, and the result is that a standard of knowledge of the healing art such as might be expected in a great University has not been insisted upon. This is clearly shown by the Report of the Visitors, which is published in the *Minutes* of the General Medical Council for 1903, just issued. The Visitors state that they were present during the entire examination of five candidates in Clinical Medicine. The following is their account of the adventures of two of these: "The first of the candidates that we heard examined was taken to the bedside of a man who presented every appearance of being in an advanced stage of phthisis. The candidate was told to interrogate the patient; and—having elicited from him that he had pain in the chest, severe cough, and had wasted greatly—when asked what was probably the nature of the man's illness, said that it looked like one of cardiac disease. Some surprise having been shown at this answer, he expressed the opinion that the case might be 'gastric.' He was then told to examine the patient. He first proceeded to auscultate the heart. Asked why he examined that organ first after the personal history he had obtained, and if he had found anything there to account for the man's symptoms, he hesitated, and eventually said that there was no cardiac disease. He had then to be told to examine the lungs; and was asked if he noticed any difference in movement between the two sides of the chest in respiration, and other suggestive questions. Finally he said there was a cavity in the apex of the left lung, but he could not say on what signs he based that statement. He was then directed to examine the right lung, and asked if he could detect any evidence of disease there; and it was suggested to him as to the diagnosis that both the patient's lungs were affected, the left lung more than the right. The candidate was particularly defective in his ideas as to the treatment of pulmonary phthisis, in respect to the general advice to be given, the precise instructions for the patient, and special treatment for symptoms, *e.g.*, cough. He was given 5 out of 20 marks for this case. His examiner showed him great consideration, and spent twenty-eight minutes with him on the case. This candidate's case for commentary was that of a young woman with double aortic valve disease. He wrote a fair report of the case, which he read out to the examiners, but he did not set down any diagnosis of the valvular lesion, although he gave the characteristic physical signs of it that were present. He was marked 15 out of 20 for this case, making a total of 20 out of the 40 marks assigned by the examiners for the clinical examination. Another candidate was told to examine the greatly enlarged abdomen of a boy and to make

out what the cause of the enlargement was. He did not ascertain, until the examiner told him, that the patient's liver was greatly enlarged. Asked what this enlargement was due to, he replied, 'alcoholic cirrhosis.' Told that such a cause was improbable in a young lad like the patient, he suggested, with equal impropriety, 'lardaceous liver.' The candidate was then directed to examine the boy's heart, and at once found 'a murmur.' (There was a double mitral murmur). He then said it was a 'cardiac liver.' Notwithstanding this candidate's deficiency in clinical acumen, he was given 10 out of 20 marks. His case for commentary was that of a young woman with nephritis, after probable scarlet fever. The report he wrote upon the case was fairly good, except that he gave neither diagnosis nor treatment. When examined orally on the case, however, he stated its probable nature. But he was 'weak' on the pathological changes in the kidney in cases of scarlatinal nephritis and upon the prognosis in such cases as compared with cases of ordinary nephritis. He was able to contrast fairly the characters of the urine in different forms of renal disease. His mark for this case was 15. Total for clinical, 25 out of 40. The answer of this candidate to one of the questions on the medicine paper was endorsed by one of the examiners as being 'very meager.' Both these candidates passed. If these men are to be taken as representative specimens, it is not surprising that the Visitors reported that 'the clinical work of several of the candidates was decidedly below the average; and in passing some of them the examiners . . . were inclined to be too lenient.'" In respect of pathology and bacteriology the examination was declared to be excellent; it was only in the practical subjects that it was deficient. It should be mentioned that men do not learn their medicine, surgery and midwifery at Oxford, but for the most part at the great hospitals in London; and the clinical examiners in the instance referred to were London men. The Visitors, Sir Christopher Nixon and the late Sir George Duffey, were both Dublin men, and it is probable that racial prejudice had a certain influence on their judgment. The same factor is seen at work when Scottish examinations are "visited" by Englishmen or Irish examinations by Scotsmen. But Oxford, whose medical degrees now stand highest in the estimation of the British public, should be above all possibility of reproach.

Every now and again some one makes the public's flesh creep with sensational statements about the danger of live burial. We have even a London Association for the Prevention of Premature Burial, which exists to impress the fear of this occurrence on people's minds. This cheerful body recently held its annual meeting, at which it was pointed out that, on the admission of the Home Secretary, 10,000 persons are buried every year in England and Wales without the formality of a death certificate; and that death certificates are frequently granted by medical practitioners without any careful inspection of the body, and without the use of any special tests to ascertain whether or not life is extinct. Often, indeed, the certificate is given simply on the information of some relative or friend, by a doctor who does not take the trouble even to view the body. With a view to remedying these evils the Association has drawn up a draft Bill enacting that no certificate shall be given without a personal examination and inspection of the body, and requiring the local sanitary authorities to provide waiting mortuaries in their respective districts. Mr. William Tebb, the president of the Association, in speaking of the difficulty of verifying cases of premature burial, said that in England there were about 800,000 burials a year, and only about one body in 50,000 was exhumed. He added that in the United States, where cemeteries were frequently moved, however, a considerable number of bodies had been found in the coffins in such attitudes as proved that they must have been buried in a state of suspended animation. Moreover, he said, narrow escapes were constantly being reported; there was one case in which a lady, who was subject to trance, had twice been placed in her coffin. In an appendix to the Association's annual report a number of alleged instances of narrow escapes from premature burial are reported. At the meeting the startling announcement was made that there was a lady in the room who had twice been in her coffin, and who had her death certificate in her pocket at that moment. It appears that the lady is subject to cataleptic trances, which on three occasions are said to have placed her in imminent danger of live burial. Naturally, after so sensational a statement, she became the prey of the interviewer. To his eager ear she confided the following strange story, which I give in her own words, as reported: "My first trance was brought about by shock. I was told that all my property had been lost. The news was quite unexpected, and it sent me into hysterics. Then I passed into insensibility, and at the end of two hours my limbs began to assume the rigidity of death. My eyes were open, and I could see what was happening, but I was unable to move hand or foot or to show that life had not yet left my body. Imagine my horror, when, after being left for twenty-four hours, I was taken from bed and rolled on the floor. Pins and needles were stuck in my body in order to see whether blood would flow. Fortunately I could feel no bodily pain, but the strain on my mind was terrible. After this every one gave me up for dead. 'Poor lady, I am afraid she is now out of all earthly suffering,' I remember hearing the doctor say. Oh! the terror of that moment! Worse was, however, to come, for the order for my coffin was given. When the undertaker's men came to measure me I tried to shriek aloud, but not a sound came from my bloodless lips. I could not have been more helpless had the Angel of Death in reality taken my soul. The final agony came when my coffin was brought into the room. At sight of that gruesome object placed by my beside, I felt as if my brain—or what was left of it—would finally break under its futile efforts to assert itself. I then lapsed into unconsciousness for the first time for forty-eight hours." Her daughter, however, had never quite given up hope, and she rose from her bed in the middle of the night to visit her mother for the last time. As she gazed on the body she thought she saw a movement of the eyelids. Hastily summoning the servants, she held a bottle of strong smelling-salts to the nostrils, and in her agitation spilt part of the contents over the unconscious woman's face. "At this," said the lady, "I heaved a deep sigh, and suddenly sat up in my bed. Saved by my daughter's love and energy." The heroine of this story is said to be a "Doctor of Psychology"—a degree, by the way, unknown to the universities of this country—and the tone of her narrative would be sufficient, without the history of cataleptic trances, to show that she is highly neurotic. But, though the story is highly colored, there seems to be no reason to doubt its substantial truth. Perhaps the medical profession is a little too prone to scoff at the possibility of such occurrences. Yet in some cases, at any rate, similar facts are well authenticated. Some forty years ago there was a discussion on premature burial in the French Senate, and the subject was treated by most of the speakers in the usual spirit of skepticism. Then the Cardinal Archbishop of Bordeaux—Donnet, I think, was his name—arose and told how at a great ecclesiastical function in very hot weather a young priest fell down, to all appearance insensible. He was removed to his dwelling, but all attempts to revive him proved

futile. He was pronounced to be dead, and in due course the body was placed in a coffin and taken to a church for the funeral rites. The supposed corpse heard all that passed, and was fully aware of the dreadful danger that threatened him, but could not move hand or foot, nor utter a sound. Just in the nick of time he heard the voice of a friend whom he had not seen since childhood. This quickened the paralyzed nerve centers into life, and saved him from a premature grave. The Cardinal's story was received with ironical laughter and calls for the name of the priest. A solemn silence came over the assembly when the venerable prelate replied, "Gentlemen, the young priest who thus narrowly escaped a hideous death now stands before you!"

At the annual meeting of the London School of Medicine for Women, which was held the other day, the report of the Council for 1902-3 was presented. The record of the year's work was very satisfactory; no fewer than forty students passed their final examinations and obtained the legal qualification to practice. Twenty-two of these took the M.B. Degree of the University of London, four the M.B. Degree of the University of Durham, one that of the University of Edinburgh, eight the Diploma of the Society of Apothecaries, and five the License of the Conjoint Colleges of Scotland. Neither Oxford nor Cambridge yet admits women to degrees in medicine or in any other faculty. Several exhibitions and scholarships were also won by girl students, upon one of whom was conferred the distinction of the Fellowship of the Royal College of Surgeons of Ireland. Several hospitals and infirmaries have for the first time appointed women to resident posts. Miss Alice Johnson, M.D., was selected from a large number of candidates as Medical Officer to the Lambeth Poor-Law School at Norwood. The Polyclinic and Medical Graduates' College has decided to admit medical women to all its work on the same terms as men. There are at present 200 students working at the school. Of these a third will go abroad as medical missionaries, while the others will spread themselves over London and the Provinces. According to the Secretary of the School the prejudice against the woman doctor is fast dying in this country and she is now generally accepted on her merits. It cannot be said, however, that in a scientific sense she has so far justified her existence here; and in the field of practice only one or two female practitioners have won anything that can be called distinction.

TYPHOID EPIDEMIOLOGY.

(Continued from Page 372.)

The village of Rathsweiler is built, as are the majority of the villages in Elsass, practically along one street, which is generally the highway of the district. It consists of 70 houses, the distribution of which is shown in the plan, copied from one prepared by the schoolmaster of the place. The houses themselves are generally of the most modest construction; the majority possess two stories, and no substructure. Except one or two, which are of stone, or partly of stone, all are built of wood. The buildings are so constructed as to accommodate both the owner's family, and the more valuable of his cattle, such as the horse and cows; the pigs and geese are, as a rule, relegated to the barn. As one enters such a building, one passes by a small door to one side of the entrance hall, into the stable, while, on the right, is the living room. On the same floor is the kitchen, and perhaps a sleeping room; on the floor above are other sleeping rooms. Closets or toilet rooms form no part of such an establishment. In the winter, the older members of the family make use of the stable, while the ejecta of the younger members are deposited in some receptacle which is emptied either there, or on the "Misthaufen" (dunghill) in the yard. In the summer, the act of defecation is frequently performed out of doors. The washing of the family linen and eating utensils is very often performed at the wells, or in the yard, with water brought thither. Another element

in the hygienic conditions, to which some importance must be attached, is the ubiquitous "Misthaufen." Before every house is the dung heap, which is replenished as often as occasion demands from the feces of man and beast, which have accumulated in the stable. At the proper seasons this heap is piled into wheelbarrows or wagons, carted to the fields, and there applied as ma-

nure. When I protested against this most unsanitary method of disposing of the infectious material, the mayor informed me that the Misthaufen was the most valuable of the family assets: "Not even a beggar would stop at a door without its Misthaufen." The wells are of two classes, public and private, the location of both is in every case denoted on the accompanying plan. They are all of the most crude construction, being generally guarded only for a few feet, at most, from the surface by ill-fitting masonry, or defective cement; thus they are not at all immune from surface flooding. It is probable that they all take origin from the same underground stream or stratum of water, although this is a point on which I cannot speak with certainty. In one of the other villages in this district, which had attained a certain degree of prosperity owing to the possession of a valuable forest, the community was supplied by pipes with water from a well about 1½ mile distant. Upon inspection, I discovered that the top of this well lay about 4 feet from the surface, and that the masonry which lined it was anything but impervious. Above it lay a wheat field, which was periodically manured from the Misthäufen of the villagers. So much, by way of preliminary, regarding the economic and sanitary environment.

The epidemic in Rathsweiler started in March, in house No. 22 of the plan, with the widow Culli. This house possesses its own well. During the month of April, there was another case of typhoid (the second in the village) occurring in the same house. In May, all the other members of the household, who belonged to the Rauch family, presented symptoms of the disease. During the same month the next house, No. 23, contributed two victims, of the ages of seven and ten years, respectively; it is noteworthy that the older members of this household remained healthy during this period, although in the succeeding month one of them also succumbed. The people in this house were accustomed to get their water, as indicated on the chart by the arrow, from the well belonging to house No. 24. During the same month of May, house No. 10, which lies just opposite to No. 22, contributed one victim, a Rauscher, to the list; the members of this household got their water from the public well marked A. During the same month, two other members of an allied Rauscher family, living a step from house No. 10, in No. 64, fell sick of the disease. These also took their water from the same public well A; it will be observed that up to this time the other families supplied from this well remained apparently healthy. In house No. 32, owned by the Rauchs, who are near relatives of those in No. 22, in which, it will be remembered, the epidemic originated, a little Rauch child, of the age of seven years, presented symptoms about May 15. Very soon thereafter, a person named Ebi, aged thirty-two years, living in the neighboring house, No. 33, and in No. 28 a child of ten years, named Pfister, also became victims of the disease. This last set of three cases were all supplied with water from well B; yet, at this time, no other house of the same water-supply group contained any case. It now becomes very difficult to follow the course of the epidemic, inasmuch as three different centers have become established, namely, house No. 22, house No. 32, and house No. 64. House No. 23, which in May had contributed two victims, presented a third in the beginning of June, and house No. 24 gave one in June, another in July. Houses Nos. 25 and 26 each had one typhoid patient in July. Within the succeeding months, the houses running in the opposite direction from Nos. 23 and 10, namely, Nos. 20, 12, 14, 15, 16, and 3, had also become infected. The second center, house No. 32, had a second case in June, as did also No. 28, and the house directly opposite, No. 58. Houses Nos. 26 and 25, 33 and 34, 58, and 41 and 43, all had patients during July. From the third center, house No. 64, the infection reached No. 63 in June, and No. 62 had one case in July, another in August. This list about exhausts the cases in Rathsweiler in the epidemic of 1902, at least so far as they were identified. As a pendant, I should like to relate the occurrence of two other cases, which historically, at least, belong to this epidemic. During July, the minister of the neighboring village of Bütten felt impelled by his spiritual calling to visit the stricken town of Rathsweiler, which had no resident preacher. He had been warned of the danger of infection, and most scrupulously avoided touching his lips with food or drink during his brief visit of a few hours. Within two or three weeks, however, he developed a very severe typhoid, which remained the only case in Bütten, with the exception of his maid-servant, who fell sick shortly after him.

In describing the course of the epidemic, I have purposely presented it in the manner in which it seems to me to have made its progress, namely, from house to house. When a well becomes contaminated, and acts as a source of infection to the houses within the area which it supplies, we may reasonably expect two results: First, the typhoid appears like an explosion, and within a short time produces more or less of a pandemic. Second, fresh cases very soon cease to occur, inasmuch as there is a natural tendency of wells to self-purification, by virtue of the greater reproductive and vegetative activity of the non-pathogenic organisms which it contains. The epidemic of Rathsweiler, however, presents neither of these characteristics; it ran for five months. During this period it crept from house to house, heedless, apparently, of such barriers as are afforded by an independent water-supply, as exemplified by houses Nos. 22, 23 and 24. In some cases, its career was modified by infections due to personal intercourse, as illustrated by the members of the Rauscher households; but in no set of cases does there seem to have been any relation between the water supply and the course of the epidemic. One is induced to conclude that in the epidemic of Rathsweiler the circumstantial evidence points most strongly to a personal transmission of the infection, as long ago urged by Trousseau, and to the complete innocence of the water-supply in its dissemination. This is the more surprising, in view of the fact, as pointed out in the preliminary statement, that there was every possible occasion for the contamination of the wells by the surface drainage, which certainly carried particles of infected feces from the Misthäufen (dunghills).

If, then, Koch be justified in his assertion that "contact-infection" plays so large a rôle in these epidemics, it becomes important to inquire into the details of its workings. Koch himself supplies many instances. Nurses in washing or bathing typhoid cases *may* infect their hands or faces, and subsequently inadvertently transfer the particles to their mouths. Those who wash the infected linen are, of course, in particular danger. It is hardly necessary, perhaps, to explain that "contact-infection," so-called, does not imply the existence of an external portal of infection, *e.g.*, the skin. It is admitted that the germs in every case enter the body through the mouth. The point emphasized by the phrase is that the infection is direct, not mediated by a common water supply. One who drinks out of an infected glass is, in this sense, the victim of a "contact-infection." As a rule, however, it would seem that the hands first become contaminated, and then carry the poison to the mouth. Thus it is that anyone who enters the sickroom, who touches the hand of the patient, runs the risk of

infection. Koch goes so far as to warn men against laying a cigar down in an infected house, for infected dirt and dust lodge everywhere. To me, it always seemed that the greatest element of danger is the Misthaufen. Here, if anywhere, the typhoid bacillus finds a favorable environment, and the opportunity to prolong its life. The children, playing on their hands and knees in the yard, are almost certain to pick up infection, and to carry it to more distant families, as illustrated in the epidemic. Moreover, the men of the household, in removing the dung to the fields, are again very dangerously exposed. This is a source of peril which, I believe, hardly exists under our own conditions. The important therapeutic and prophylactic deduction from all these arguments is that each case should, as far as possible, be isolated. The family and friends should be excluded from admission to his room or house, and one person should be made responsible for the nursing. The dead are also to be kept isolated, and to be buried as early as possible. All excreta are, of course, to be at once disinfected; a careful watch is to be kept over the urine, which is often swarming with typhoid germs for months after recovery. In addition to observing all these precautions, we employed the services of a disinfector, who had to steam all the clothes and linen which had come in contact with the sick. These, and these alone, were the measures we took for controlling the epidemic; the water supply we completely neglected. Our results, nevertheless, were quite satisfactory, inasmuch as no new cases developed within two weeks after these prophylactic measures had been instituted. Parenthetically, I may state that many of the wells were frequently examined, chiefly by Altschuler's method, for the typhoid bacillus, but never with any success. This was done in the Strassburg Institute. I am, however, far from believing that such negative results may be taken as final evidence; the problem of identifying typhoid germs under such conditions has, unfortunately, not yet been solved.

In connection with prophylactic isolation, Koch has laid great stress upon the unidentified cases of typhoid, or typhus levissima. These cases are not sick enough to go to bed, yet carry about with them enormous numbers of typhoid germs. Every epidemic is accompanied by such cases, which are marked only by very slight symptoms—malaise, headache, bronchitis, or diarrhea. Nevertheless, if the stools of these individuals be carefully examined, or their urine after a time, it is generally possible to isolate the *agens morbi* in the shape of the typhoid bacillus. It goes without saying that just these cases are most dangerous to the community, inasmuch as they act as carriers and disseminators of the infection. Naturally, the danger is greatest under such conditions as prevail in villages such as Rathsweiler, and becomes minimal in large cities, with good sewage and drainage systems. This holds true, doubtless, of every kind of contact-infection; yet, as shown by hospital records, it is under all circumstances a factor to be reckoned as highly important.

I had originally intended to describe in some detail the work of the bacteriological laboratory in Diemeringen, but my letter has already assumed such disproportionate dimensions that this aspect of the "fliegende Station" must be excluded from consideration. I would but state that not only the Widal, but cultivation of the bacillus from the stools, urine, and, rarely, the sputum, were resorted to for the identification of every case of the disease.

Respectfully,

Richard Weil, M.D.,

Pathologist to the German Hospital, New York.

New York, Feb. 4, 1904.

THE MEDICAL SERVICE OF THE JAPANESE ARMY.

To the Editor of the Medical News:

Dear Sir: During the war between China and Japan in 1894-95 Sir William Taylor, M.D., now Director-General of the Medical Service of the British Army accompanied the Japanese force in the capacity of Attaché. The outcome of his observations was a valuable Report on the Medico-military Arrangements of the Japanese Army in the Field. It may be of interest at the present time to give a brief summary of his conclusions. He formed the opinion that "the organization of field hospitals, dressing stations, and bearer companies in the Japanese Army, is very complete, and that the regulations go into and deal with their administration in great detail. Neither of these organizations, however, was tried severely during the war; indeed, instead of employing the authorized number of field hospitals the work was carried on well with under one-third of them. The positions of the dressing stations were well selected, their sections arranged, and the wounded attended to as well as in any well-organized hospital in time of peace. Straw was spread under the shade of trees for the reception section, the patients were given beef tea or such other restoratives as were considered necessary, the regulations as to arms, accoutrements, personal properties, etc., were carried out, and the wounded carried to the dressing or operating section in the order of severity of the wounds received. Taylor says: "I saw nine wounded men brought into one dressing station in ten minutes, and, in turn, all properly attended to and sent back to the field hospital, which was in a village about 300 yards off. Everything in the way of equipment was there, and all the requirements for antiseptic surgery after the most approved methods. The instruments were laid out in sterilizing solution, and plentiful supplies of antiseptic dressings at hand. The first field dressings were removed, if necessary, the wounds carefully examined and dressed again after such treatment as was considered necessary. The tallies were always first examined. On one or two instances they told of good work having been done in the fighting line, when the lives of several men were saved by the ligature of arteries, or the timely application of a field tourniquet. There was no confusion or hurry; everything was done quietly and in that way which shows that all concerned were quite conversant with the duties they had to perform, and thoroughly competent; in short, there was every evidence of that efficiency which can only be the result of the most careful and complete training. At Wei-hai-wie, on January 30, during the attack, the efficiency of the regimental medical organization and of the bearer companies was demonstrated in the most splendid way. A regiment which had advanced into the middle of a flat sandy beach on the south side of the harbor suddenly found itself under the fire of three Chinese ships and four torpedo boats, all of which turned upon it their quick-firing guns from a distance of not more than 300 or 400 yards; in a very few seconds many men had been killed or wounded, and it was evident the regiment would soon be annihilated. The men were then made to lie down, and soon after they began to crawl or walk off the beach and get into the shelter of a ravine at some distance; there the regiment reformed; the dead and wounded were still on the field. Before all the men had reached the shelter of the ravine the medical officers, one by one, and at some distance from each other, accompanied each by two or more stretchers and some attendants, were seen to walk in different directions across the beach in the face of an incessant fire of bullets, which plowed up the sand in every direction.

They picked up the dead and sent them back, attended to and dressed the wounds of those still living, and in twenty minutes, stretcher bearers, attendants, and medical officers, walking quietly and coolly away, had removed every dead and wounded officer and man from the beach, the Chinese ships having kept up a continuous and terrific fire upon them all the time. It was a splendid deed of heroism which can never be forgotten, and of which the Japanese Army should be proud; but it was done as a matter of course and in the routine of duty, and we who saw it, and could not resist shouting 'bravo!' have never heard it referred to or spoken of. It will, however, be an enduring proof of the efficiency in the field of the Japanese medical service."

With regard to hospital ships and transports, Sir William Taylor says: "There were no hospital ships for the army. There was one which accompanied the fleet. She was a steel screw steamship of 2900.59 gross and 1645.2 net tonnage, and 387 horse power. She had accommodation for 50 officers and 200 men. The officers' accommodation was in the first-class cabins, which were roomy, well lighted, and warmed with steam-pipes, and were well ventilated. Each cabin had two good-sized iron beds, or cots, with wire-woven mattresses. About half were on the upper deck, and were particularly light and airy. They were reserved for the serious cases. They were lighted, as was every other part of the ship, with electric light. An operating room had been made by throwing two of these cabins, on the port side, into one, and putting in large glass windows. A special electric light was fitted over the operating table, and there was also a movable hand light. There was a plentiful supply of water in the room, which was also fitted with all the latest modern appliances for the special purpose for which it was intended. The second-class cabins were kept for warrant and petty officers. They were of similar construction, though not so highly finished as the first-class cabins. Each cabin had four iron cots with wire-woven mattresses. They were well lighted and warmed by steam. The men were accommodated in the freight hold, and on the main deck forward. There was space for 50 men on the main deck forward, 80 on the lower deck, and 70 aft, under the first-class saloon. They lay on platforms—not in bunks—raised about 18 inches from the deck. The space allowed for each man was 7 feet by 4½ feet. Each had a quilted mattress of cotton, a Japanese pillow, a pair of white sheets and two blankets marked with a red cross. The clothing for each consisted of a good flannel shirt and the usual wide-sleeved quilted, hospital gown, with a red cross on each sleeve. The patients were scrupulously clean and comfortable. There was a senior naval medical officer in charge, with six other officers under him, and a staff of pharmaceutists and attendants. There was a well-equipped dispensary and a liberal supply of surgical appliances and materials. The officer in charge had only to ask for what he wanted in the way of equipment; there was no scale of supply. There was a very good form of stretcher on board for embarking and disembarking helpless patients. It was made of two long bamboos with canvas between, the latter kept stretched by two cross-pieces of wood with iron rings at each end, which slipped on to the bamboos and kept them apart.

"There were some well-equipped military hospital transports. At the beginning of the war, transports carrying troops were not provided with medical officers, or any establishment, and unless the medical officers (or some of them) of a regiment happened to be on board, there was no medical aid at all. Many soldiers and followers were thus sent in transports without medical assistants, further than what the captain carried in the medicine chest he carried on passenger service. Later, it was found necessary to have a medical officer in each transport. He was generally a member of the Red Cross Society, and had as equipment a medicine chest belonging to the Society. There were also a pharmaceutist and two attendants, and a small quantity of hospital clothing. Besides the foregoing, after cholera appeared among the troops, appliances and materials for disinfecting were carried on board each transport, and when cases occurred at sea, that part of the ship in which it appeared was thoroughly disinfected, that is, as thoroughly as was possible in a crowded ship, during a voyage."

Under the head of Sanitary Arrangements, Sir W. Taylor says that "Although the regulations for the medical department in the field were called 'Orders for the Field Sanitary Service,' they did not refer to questions of sanitation at all. Such subjects as conservancy, latrines, urinals, prevention of the fouling of wells, or other sources of water supply were not dealt with. In short, there were no regulations with a view to ensuring satisfactory sanitary conditions. In practice, the same want of thought for all sanitary precautions, even the most ordinary, was evident. Hundreds of dead bodies were left for days where they fell, often in heaps, in the narrow streets and lanes of towns into which the army had entered to occupy permanently. Many hundreds were left lying for weeks, and even months, in the neighborhood of occupied towns, where, from the conformation of the country, all decaying or decayed matter must be washed down by the rain into wells. Even when it was thought advisable to bury them, it was done in such a perfunctory way that the burial was an outrageous farce. Bodies were heaped up in a shallow trench, not a foot deep, and merely covered with a sprinkling of earth, which the first shower must wash off. Some were thus sprinkled over without even the pretence of a trench; others were covered over in the drains for surface water. Corpses floated about in the harbor for days, or were laid in a shallow groove in the sand at low water, and washed up again when the tide rose. The surface soil all round such places was polluted, poisoned, and made pestilential, and only hot weather was wanted to make the atmosphere the same. Dogs scraped away the scanty sprinkling of earth in many of these cases, and tore the bodies to pieces, dragging the intestines all over the place; and, incomprehensible as it may seem, Chinese, belonging to the towns, looked on without thinking or driving the dogs from their ghastly feast upon the bodies of their own countrymen. Even in the neighborhood of hospitals the same indifference to surroundings, often painfully foul and noxious, was quite general. At one of the most important hospitals on the line of communications, the condition of the immediate neighborhood was so filthy that the stench was almost unbearable. Inside everything was clean and nice, but within a few yards of the entrance was a heap of filth which was the collection of months, or, perhaps, years, on which were lying rotten fish, dead cats, shellfish, and all sorts of similar things in every stage of putrescence. This seemingly universal indifference to the most insanitary surroundings existed till very near the end of the campaign. Later great activity was observed in sanitary measures, and everything was done to improve existing conditions. Temporary latrines and urinals were put up in different parts of the occupied towns, and drains made, sometimes, as at Kinchow, at very great expense. There, an elaborate system of drainage and sewerage was carried out, public latrines and urinals erected, and a regular system of conservancy established; wells were also cleansed and protected. The result was most satisfactory, as the town, which, at one time had every condition that was most likely to produce disease or epi-

demic, was almost free from diseases due to insanitary causes. It was no light undertaking to put into good sanitary state a town which had been occupied for hundreds of years by the filthiest people in the world, and their success at Kinchow only showed what the Japanese authorities could do when they took the matter into consideration, and made up their minds to attend to sanitation. It would be agreeable, as well as satisfactory, to be able to think that the neglect of ordinary sanitary precautions was at first due to uncertainty of occupation, or some similar cause, but that is not possible, for nothing could excuse the condition of the surroundings of some of the hospitals, as above described, even if they were only to be occupied for a few days."

Under the head of Water Supply, Taylor says that on a campaign like that in which the Japanese Army was engaged there was not much choice of water, and the troops were obliged to use what they could get. "Each battalion carries with it a box containing appliances and materials for the chemical analysis of water, and it is the duty of one of the medical officers to go on ahead to any proposed halting place, for the purpose of examining and reporting upon the water in the different wells of the place. That could not always be done in war time, but, when a village or town had been entered, no water was supposed to be drunk, or used for cooking, until the medical officer had reported upon it. Each battalion is directed to carry two wooden filters, bucket-shaped, with a layer of fine sand at the bottom, then one of coarse sand, and on the top one of gravel, each layer being separated by a piece of sponge cloth (? asbestos cloth). These filters were not always used. The water, it was ordered, should be boiled before being used for drinking, but that order was not always, or even commonly, carried out. It seemed to be nobody's duty to see it obeyed; besides, there was very often the greatest scarcity of fuel, so that the water could not be boiled. Each officer is supposed to possess a small pocket filter made of brass, filled with charcoal, with a piece of sponge over each opening between it and the charcoal. Two India rubber tubes were attached, one on each side, to small projecting openings in the brass; one of these tubes was put into the water and the other into the mouth. The Japanese, as a rule, drink very little water or, instead, I should say, very little cold water. They drink small quantities of the weak tea peculiar to the country, and that tea was always to be had with the army, except on occasions when men were away from the main body and all supplies. They were very fond of eating snow, and many of them devoured large quantities of it, but I could trace or hear of no cases of disease due to that practice."

The treatment of gunshot wounds is described in considerable detail. "The first field dressing consists of two folded pieces of corrosive sublimate gauze, a piece of waterproof paper, and a triangular bandage. That is the only protection until the dressing station is reached. There, a supply of almost every kind of antiseptic dressing—carbolic acid, corrosive sublimate, iodoform, boric acid, oakum, etc., was available. A solution of corrosive sublimate, 1:1000, was generally used for washing and irrigating wounds, which were often also dusted with boric acid or iodoform. They were dressed with a pad of corrosive sublimate wool, or with Dr. Kikuchi's straw ash pad. The latter was very extensively used, as being much more economical than the former, and could be made anywhere. It consisted of the ashes of burnt straw freed from all grit, and put into bags of antiseptic gauze, which were kept ready made in all sizes. It was applied directly to the wound and a bandage put over it. If there was little or no discharge from the wound, the pad was applied dry, but, if discharging freely, the pad was first soaked with corrosive sublimate solution. When these pads were not used, which was very rarely, especially in the First Division field hospitals, the dressing consisted of corrosive sublimate wool, a piece of protective, some common wool, and a bandage. Drainage tubes were always used where necessary, and when the dressings were changed the wounds were always thoroughly well irrigated. Loose pieces of bone in a gunshot wound were never removed forcibly, but were left to come away in the discharge or irrigations. Although there was very often considerable overcrowding in some of the buildings used for hospital purposes, the rooms being small, the results of the above form of treatment were uniformly good."

On the whole, with the exception of sanitation, the Director-General of the Medical Service of the British Army forms a very favorable opinion of the medical arrangements of the Japanese army. They were well devised and worked excellently in practice. Their surgery and medicine were quite up to the standard of modern science; and in the matter of sanitation they showed themselves ready to learn by experience.

February 15, 1904.

SPECIAL ARTICLE.

EXCURSIONS IN OLD NEW YORK MEDICINE.—IV.

THE ELGIN BOTANICAL GARDEN.

The recent announcement that the Board of Trustees of Columbia University propose to sell the block between Forty-seventh and Forty-eighth streets and Fifth and Sixth avenues has recalled public attention to a very important old-time medical landmark in the city's growth. There are three other blocks in this neighborhood also owned by Columbia College, and these combined properties once formed the Elgin Botanical Garden which in 1801 was bought by Dr. Hosack and called the Elgin Botanical Garden, after the place of the birth of his father, Alexander Hosack, who was a native of the town of Elgin, Murrayshire, Scotland. When Dr. Hosack bought the ground it was far outside of the city, but now, after the lapse of a century, has become one of the most valuable pieces of property on Manhattan Island.

Some of the recent estimates of its present value are of great interest in this matter. One broker, who was approached on the subject, considered that exclusive of the Fifth Avenue frontage, a conservative estimate of all the property would be about $2,000 a front foot. This would make a value on the side streets of nearly $3,000,000, while the Fifth Avenue block front would be worth at least $1,500,000, making a grand total value of $4,500,000. This is probably too conservative an estimate. The property passed out of the possession of Dr. Hosack in 1814, who sold it to the State of New York. During the course of the negotiations for its sale, an expert in property of the time, under date of January 30, 1810, said: "In reply to your note of the 26th instant, requesting my opinion of the value per acre of your ground or garden, were I in want of such a piece of ground I should think it a good purchase at $2,250, and not a bad one at $2,500. In a few years I have no doubt it will be worth much more."

It is very evident that the expert in property had no idea of how much more it would come some time to be worth. A number of letters show that New York land in this vicinity at that time was worth between $2,500 and $4,000 an acre. Accordingly the botanical garden was sold for $2,500 per acre, and the buildings thereon

for an additional $24,300. The whole sum received by Dr. Hosack amount to nearly $75,000.

A very curious bit of history is connected with the subsequent transfer of this plot of ground, that had formed the Elgin Botanical Garden, to Columbia College. Before the admission of Vermont as a State—this being the first one of the States admitted in addition to the thirteen original colonies, after the Revolution and organization of the Federal Government, New York claimed certain portions of land on the other side of Lake Champlain, which now constitute portions of Vermont. The territory had always been in dispute, but New York State, as if formally to assert her rights, had granted a township of land in this territory to Columbia College, which from being King's College, now came to be looked upon as a special protégé of the State. After the admission of Vermont as a State by the United States Government, the drawing of the boundary lines left this township on the Vermont side of the line and consequently nullified the advantage that Columbia was expected to derive from it. As compensation for this the botanical gardens were granted to the University. The whole story of the grant is to be found in a pamphlet known as a statement of facts relating to the establishment and progress of the Elgin Botanical Garden, and Subsequent Disposal of Same to the State of New York, by David Hosack, M.D., which was printed in New York by C. S. Van Winkle, of No. 56 Pine Street, in 1811. This pamphlet may be found in Volume VI of Bound Medical Pamphlets at the New York Academy of Medicine.

Dr. Hosack, in preparation for properly influencing the legislature to make this purchase, and giving them definite data as to the value of the institution and property, obtained the opinions of a number of learned scientific societies, especially of such medical societies as were then in existence. The act under which the purchase of the Botanical Garden was made by the State was entitled An Act for Promoting Medical Science in the State of New York. One of the most influential documents presented in favor of the act consisted of excerpts from the proceedings of the Medical Society of the County of Saratoga, of the Medical Society of the County of Ulster, of the Medical Society of the County of Dutchess, and of the Medical Society of the County of Niagara, which were, it is believed, the only county medical societies in existence at the time (this was 1809), though the State Medical Society had been established some three years before, mainly through the instrumentality of the members of the County Medical Society of Saratoga.

The resolution of the State Medical Society suggests an alternative method of obtaining funds in order to remunerate Dr. Hosack and preserve the Botanical Gardens for the benefit of the medical profession in case the legislature should refuse to pass the necessary enabling act. Their resolution, which runs as follows, shows that public lotteries had not as yet come into that State of objectionableness in which they now are: "Resolved, That the Medical Society of the State of New York do unite with the preceding public bodies (scientific societies of various kinds), in an application to the legislature to solicit them to purchase the Botanical Establishment of Dr. David Hosack, if consistent with the funds of the State; or otherwise to grant a lottery for his remuneration and the establishment be so managed under the direction of the legislature as may be most conducive to the diffusion of medical science throughout the State.

"Done by order of the Society at their meeting in Albany held the seventh day of February, 1810. Nicholas Romayne, M.D., President of the Medical Society of the State. John Stearns, Secretary."

This Dr. John Stearns, of course, would be the distinguished physician who was afterward the first president of the New York Academy of Medicine, and who was one of the chief organizers of the Medical Society of the State of New York. It is to him, as was noted in a previous number of Excursions in Old New York Medicine, that the medical profession owes the introduction to America of powdered ergot under the significant name of pulvis parturiens.

One of the arguments that influenced legislators most in the purchase of the Botanical Gardens was the fact that realizing the benefit to be derived from such an institution as Dr. Hosack had established, his being the first establishment of the kind ever attempted in the United States, at least three other States, Massachusetts, Maryland and South Carolina, had proceeded to the enaction of such measures as gave them the benefit of like institutions.

In closing this discussion of the sale of his botanical gardens, Dr. Hosack, after giving all the formal documents which passed between him and the legislature, as also the permits from the city for the closure of the streets that ran through this neighborhood, says:

"From the preceding documents, the reader will be enabled to form some opinion of the many difficulties I have had to encounter in the establishment of the botanic garden. It will also be perceived that as a useful and necessary institution, it has been sanctioned by the approbation, not only of the medical profession throughout the State, but by the learned of every profession, and by many others of our most respectable citizens; that in every instance, when introduced to the notice of the legislature, it has met with a favorable reception, and has always been considered as deserving of legislative provision; that during the discussion which took place, in the last and the preceding years, relative to the purchase of the establishment by the State, the most influential members, both of the senate and assembly, however divided in their political sentiments, united in giving it their decided and liberal support. It will also appear from an examination of the act which was passed, that the purchase of the garden was to be made upon a fair and equitable valuation; that such valuation has accordingly been made by five of our most respectable citizens, chosen by the commissioners of the land office—that the appraisers formed their opinion of the value of the property, not only from their own personal knowledge, but also from the estimates which they received from many other reputable and disinterested individuals; and that, after a due examination of the condition of the act, they considered the delay of payment as constituting a necessary part of the valuation—that they accordingly formed their estimate of the property, amounting, exclusive of the plants, to the sum of $103,137, which estimate was presented to the commissioners of the land office in June, 1810. It has also been stated, that at a meeting of the commissioners of the land office in September following, the appraisers were called upon to designate the value of the garden, exclusive of any allowance for the delay of payment; and that the appraisers, in reply, stated the value, exclusive of any allowance for the distant period of payment, in other words, the price if paid for in cash at the time of the purchase, at $74,288.75—that at a subsequent meeting of the commissioners of the land office, held in the month of October following, they made me an offer of the last-mentioned amount—that I acceded to the terms proposed, and immediately contracted with the corporation of the city for a release of the quit rent, and of the streets that had been reserved upon the property; and that, having thus obtained a perfect title, the contract with the State was thereupon completed."

Dr. Hosack then adds, with regard to the real value

of the property, data, which show that his sale to the State was really dictated by unselfish motives.

"I have already observed, that I was influenced, in my acceptance of the terms proposed, by two considerations: First, that the legislature, in their construction of the terms and spirit of the act that had been passed, would agree with the appraisers in the propriety of including the interest of the purchase money in their valuation, for the period of time to which the payment might be deferred; secondly, that I accepted the same as a duty to my friends, to whose kindness I had been indebted, and by whose aid I had been enabled to support the establishment. But when the legislature are informed, that independent of the time and attention which I have bestowed on that institution, for nearly ten years, exclusive of the enhanced value of the property since its first purchase, and the additional expenses I have since incurred in obtaining a release of the streets that had been reserved by the corporation, that my disbursements, with the addition of simple interest for five years, have exceeded the sum I am to receive, at the time provided by the act, upward of $28,000, I feel the fullest confidence that the same liberal views which induced the legislature to make so large and honorable an appropriation for the promotion of science, will also incline them to sanction the appraisement as at first presented to the land office. To their decision I respectfully submit."

Quite apart from any monetary considerations, it is with eminent propriety that the Assembly Hall of the New York Academy of Medicine is called after Dr. Hosack, who was beyond all doubt one of the most professionally faithful and distinguished medical men that the New York profession has ever had among its members. Now that current events and interest in this property have called popular attention to Dr. Hosack once more (his name and career have surely always been familiar to the members of the medical profession, who are interested in the history of medicine, as they should be), a short sketch of his life and times will be given in the near future, for he lived at a transition period when stirring events disturbed the monotony of existence, and once, at least, during the famous Doctors' Mob in New York Dr. Hosack was in danger of his life, simply because he was a medical student.

SOCIETY PROCEEDINGS.

NORTH BRANCH PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, January 13, 1904.

The President, Samuel Wolfe, M.D., in the Chair.

Physicians' Relations.—This was the subject of the address of the retiring chairman, and was read by Dr. H. Brooker Mills, who, after remarking upon the value of the organization of branches of the County Society in this city, considered the subject of "Physicians' Relations," (1) to their patients; (2) to the fellow members of the profession, especially consultants; and (3) to themselves. In regard to the first question, he believed that many unnecessary complications could be avoided by properly "training" the patient. In regard to the second question he deprecated the practice of the division of the consultant's fee with the attending physician, and believed that the same should be regulated according to the patient's ability. In regard to the physician's duty to himself, he urged that the medical man take sufficient rest to enable him to perform services of the highest character.

Thorough Organization.—Dr. A. M. Eaton in discussing this paper urged the importance of thorough organization of the medical profession, believed that more attention should be given to the business side, and also felt that through organization, much of the imposition which is practised by the undeserving upon the hospital clinics could be avoided.

The Diagnosis and Treatment of Internal Hemorrhoids.—This was the title of a paper read by Dr. Herman A. Brav, in which he defined hemorrhoids as varicosities of the middle and superior hemorrhoidal veins sometimes associated with eversion of the rectal mucous membrane, and always accompanied by more or less pain and tenderness. He divided them into (1) capillary hemorrhoids; (2) arterial hemorrhoids, and (3) hemorrhoidal tumors, which may also be termed, respectively, the first, second and third stages. In view of the fact that these conditions are also accompanied by hemorrhage, pain, protrusion and discharge of mucus, internal hemorrhoids are frequently confounded with cancer of the rectum, polypus of the rectum and prolapse of the rectum. The conflict is particularly apt to occur in children, in whom polypus and prolapse are not uncommon, and internal hemorrhoids, while they do occur, are rare. Polypus and prolapse can be distinguished from hemorrhoids by a careful digital examination, which will reveal the presence of a pedicle to which the growth is attached, and malignant disease can be distinguished by the hard growths on the rectal wall. He reported the case of a woman, aged seventy years, which had been diagnosed as internal piles, the patient having suffered from rectal hemorrhages, and a constant desire to evacuate the bowels. Digital examination in the lateral and semiprone position revealed nothing, but digital examination in the erect position with the patient straining down showed a malignant stricture about four inches above the anus. He also referred to the case of a boy in which a polypus had been diagnosed as internal hemorrhoids. The first stage of the hemorrhoidal development is the most difficult of diagnosis, and in many cases aid will be secured in this direction by making the examination immediately after the bowels have been emptied by means of an enema and having the patient strain down.

In regard to the treatment, he remarked that this should be considered with reference to the cause of the condition, which may be either constipation, retroversion of the uterus, foreign body in the rectum, pregnancy, straining during micturition, as from stricture or enlarged prostate. He divided it into two heads, the palliative treatment and radical cure by means of operation. He did not believe that palliative treatment was effective in the third stage, but felt that it was successful in the first and second, and recommended that in all cases the cause of the condition be ascertained and removed, if possible. Constipation should be avoided, the diet regulated, and alcohol and tobacco used only in moderation, if permitted at all. Mild aperients, massage of the sphincter, and the injection of two ounces of olive oil at bedtime, are beneficial in regulating the bowels. Hemorrhage is most efficiently relieved by the application of cold astringents. After each defecation cold water should be injected and the addition of 10 grains of tannic acid is very efficient. As a means of palliative treatment he uses an injection of five to ten drops of a solution composed of one part of pure carbolic acid; two parts of glycerin and two parts of water. He frequently injects two or three tumors at a time, but did not recommend that more than one be injected by the novice, and the sittings should be a week apart. Following this treatment, the tumor gradually lessens in size, and in a few weeks the pain and discomfort will disappear. In the cases of strangulated piles, immediate operation should be

performed, but if the patient will not permit this, applications of lead water and laudanum lotions afford great relief, and reduce the edematous swelling, so that the piles may be replaced. He described fully the operation he performs. After tying the piles with a ligature, he does not cut them off, but inserts a rubber tube in the rectum and keeps the bowels confined for about four days, after which action is secured by means of purgatives or enema, if necessary. Next to the ligature operation, he believes the clamp and cautery operation, as performed by Henry Smith, to be the best. The patient should be kept under observation for at least three weeks after the operation, being allowed about the room after the first week or ten days, but should be in a recumbent position most of the time for the balance of the period.

Dr. Collier Ford Martin, in opening the discussion on this paper, referred to the treatment of hemorrhoids, which is of value in some cases, *i.e.*, stretching the sphincter. He felt that it was very difficult to diagnose hemorrhoids by digital examination, and alone, and stated that the method he had found most effective was the employment of a small conical or tubular speculum. In regard to the treatment by injection, he was not inclined to view this as a palliative measure, but believed that in cases adapted to its use, practically all should be cured. In fibroid piles, however, the operative treatment is very much better. In regard to the sloughing following injection, he did not believe that this was a consequence of this method of treatment, but was due to the fact that proper aseptic precautions were not employed, or too strong a solution used, or too much fluid, and it is also well in all cases in which there is the least tightness or irritability of the sphincter to divulge the same under nitrou oxide prior to the injection. The injections should be made through a tubular speculum, one at a time, and the sittings should be a week apart. He believed in the weaker solution, and he is at present using the French phenol-sodique. The piles usually disappear in about two or three weeks after the operation. He had had no experience with the ligature method.

Electro-thermo Cautery.—Dr. Frank C. Hammond referred to the electro-thermo cautery used by Dr. Andrew J. Downes, and stated that he had seen some eight or ten cases of hemorrhoids operated on with this instrument that complained of absolutely no pain. He also stated that he had seen one case operated on which was burned considerably; this, however, was done by an inexperienced operator, to which he attributed the burning rather than to any fault of the instrument.

Dr. Bray, in closing, stated that he did not believe a speculum was necessary to diagnose internal hemorroids, but that they could be better noted by a digital examination with the trained finger. In regard to the injection method, as compared with operative procedure, he believed that in order to secure a radical cure, it was necessary to inject fifty or sixty drops of carbolic acid, as the injection of a smaller amount, while it will relieve the patient, will still leave a small hardened tumor, but which will give rise to no discomfort under proper dietetic and prophylactic measures. For the radical removal of the piles he believed the ligature method was the best, and that following it came the clamp and cautery, the difficulty of the latter method being that you are apt to include healthy mucous membrane, and if too much is removed, it may lead to stricture. He stated that he had not employed the electro-thermo cautery.

Appointment of Dr. Gorgas.—It is reported that Dr. Gorgas has been appointed sanitary medical expert for the Panama Canal Commission.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Section in Clinical Medicine and Surgery.

Stated Meeting, held January 15, 1904.

Laparotomy for Gun-shot Wound.—Dr. Robert Johnson reported this case, the last of a series of five operated on during the year, without a death. Patient was a colored boy who had been shot in the abdomen and when seen one hour later was in great shock; no pulse being palpable at the wrist. Just before the accident he had eaten ice cream and cake. The wound of a 32-caliber bullet was found in Poupart's ligament and led into the abdominal cavity. Laparotomy was done through a median incision; thirteen perforations in the small intestines and eleven in the mesentery were found. All were sutured. Blood and feces were dipped out of the abdominal cavity, which was then flushed with salt solution, a large quantity of which was left in. The wound was drained with iodoform gauze. The patient made an uneventful recovery, and was well in three weeks. In a discussion as to the value of salt solution in abdominal work Dr. Baer said that he had found it useful in operating on ruptured appendix. Dr. Gardiner stated that he always washed out the abdominal cavity as a routine measure, if there was any soiling of the peritoneum. He had also found it of use in extra-uterine cases. Dr. Harrison said that good results had been obtained both by flushing and by only wiping the peritoneum, and that there were as many opinions on the subject as there were operators. Dr. Roland emphasized the value of salt solution in obstetrical practice, and particularly the use of large quantities in eclampsia.

Stated Meeting, held February 6, 1904.

Amebic Abscess of the Liver.—Dr. Beck showed two patients with this affection who had been admitted to the City Hospital within a week. Thirty-four cases of this condition have occurred at the City Hospital and four have recovered, two without and two with amebæ in the stools. The first patient was a man of thirty-two years, whose first attack of dysentery began in 1900. He gave a history of having drunk well water. The symptoms were frequent stools, chills, night-sweats, abdominal pains, loss of weight, edema of the feet and legs and blood in the stools. The amebæ were found and patient was started on quinite sulphate. Abscess formed and an operation was done on June 20, the liver being aspirated and then the abscess opened and drained. Two connecting cavities were found. Recovery was uneventful. Six months after operation no amebæ could be found and two and a half years have since elapsed with no return of symptoms. The second patient contracted dysentery at Fortress Monroe in 1888 and was discharged in 1890 from the army with incurable diarrhea. In 1894, however, his health was good, but in 1901 he began to have pain in liver, nausea and vomiting, great depression with some enlargement and tenderness of the liver, but no leucocytosis. He was operated in June, and at the end of July discharged cured. About four months later there was recurrence of all the symptoms, and in December a second operation was done. This was followed by improvement, but in June amebic dysentery reappeared which responded to treatment, only to recur again.

Dr. Gamble said that the interesting point about the first case was that amebæ left the stools after the operation. Irrigations in amebic dysentery increase the danger of perforation, for death does oc-

cur in the acute stage in spite of what the pathologists say to the contrary. To avoid this danger I have been giving quinine internally in pills whose coating is undissolved until it reaches the intestines. The patients are thus cinchonized just as malarial patients are, and the good result may be due to the toxic action of quinine on the amebæ, which belong to the same family as the malarial parasite.

Dr. Earle said that he always treated his cases with irrigations of silver nitrate and quinine, and Dr. Kirby reported having seen irrigating fluid in the abdominal cavity of amebic cases post mortem. Dr. Earle stated that a rectal tube of the sort most frequently used cannot as a matter of fact be inserted and that it really catches on the rectal folds. He always gives irrigations in the knee-chest or the Sims position, and finds no difficulty in making the irrigation run in.

Chronic Interstitial Nephritis in the Young.—A paper was read on this subject. This condition is usually seen in connection with arteriosclerosis and hence we expect it only in the later years when the causes of arteriorsclerosis have had a chance to do their work. Osler, Senator, Flint and others say that it is quite rare in children, and we would naturally expect this, inasmuch as lead poisoning, syphilis, diabetes, overeating, etc., play no important part in early years. In adults, males are affected with this form of nephritis more often than females, but in infants the case is reversed. Dickinson reported 300 cases, only one of which was under eleven years, and recently a case under fourteen years has been reported. Heubner thinks that the condition is rarely primary and always follows an acute gastritis, pneumonia or some such disease. Heredity and congenital lues may play a part, for there have been many cases showing a familiar character. Two cases were reported, the first of which was fourteen years old, and complained of bleeding from the gums. The child had poor appetite, headaches and frequent micturition, and was weak and restless. Urine contained a trace of albumin and a few casts. Death occurred three weeks after onset, and the autopsy showed an atheromatous aorta with contracted granular kidneys. The second case was eighteen years of age, and complained of frequent micturition. Her urine contained albumin, hyaline casts and a few pus cells. There was some anasarca. Autopsy showed an enlarged heart, a very small aorta and extremely contracted kidneys, the right one weighing but 18 and the left 22 grams. This relation between contracted aorta and granular kidneys has been noticed quite frequently in the literature.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, held at the New York Academy of Medicine, February 8, 1904.

Address by the Retiring President, Dr. Andrew H. Smith.—Dr. Andrew H. Smith delivered his farewell address. In it he stated that in the brief period since its organization the Association had attained a position such as is generally reached by similar bodies only after many years of laborious effort; indeed, it seemed almost to have sprung fully developed into existence. While he had endeavored to faithfully administer the trust placed in his hands, he recognized that the marked success of the Society had been due chiefly to its Executive Council, which gave shape and direction to the energies of the body at large, and particularly to the indefatigable efforts of the Secretary.

A Medical Man at the Head of the Health Department.—In closing, Dr. Smith called attention to a subject of congratulation. "For the first time since its organization," he said, "the Health Department has a medical man at its head. The insanity of our law-makers, that in express terms forbade that this should ever be the case, experienced a lucid interval at the moment when the new Charter was under revision, and now at last it is recognized that knowledge of the laws of health does not unfit a man to be President of the Health Board. . . . I am sure that I express the sentiment of the Association in felicitating the city on the one hand, and on the other, Dr. Darlington (who is a Charter Member of the Association), an esteemed member of our own profession."

Discussion on Pancreatic Diseases.—Dr. Thomas E. Satterthwaite, the President-elect, delivered his inaugural address. After a reference to the flourishing condition of the Association, it was devoted to the Pancreas and its Diseases, his remarks being designed as an introduction to a general discussion on this subject. Fifteen years ago, he said, we knew comparatively little that was definite about the pancreas. Since that time we have learned much, not only of its anatomy and physiology, but also of its diseases and their treatment. Much, however, is still unknown, and it is to be hoped that the discussion of this evening will set the whole matter in a clearer light. Dr. Satterthwaite gave a résumé of the work that has been done in reference to the pancreas. In the course of it, he said that the connection between pancreatic hemorrhage and acute pancreatitis appears to have been first noted by Rokitansky, though this relation is still somewhat obscure. The two may coexist or not. In 1885 Dr. Satterthwaite presented a case at a meeting of the New York Pathological Society, where there had been a hematoma of the pancreas, without inflammation of the gland, due, as he thought then, and still thinks, to biliary salts in the blood. On the other hand, Halstead, of Baltimore, has instanced a case where there was pancreatic inflammation in association with cholelithiasis, in which a small stone had lodged in the diverticulum of Vater and diverted the bile into the pancreatic duct, causing pancreatic suppuration and hemorrhage. In 1869 an interesting anatomical discovery was made that was destined to greatly enlarge our views as to the physiology of the pancreas. Paul Langerhans, of Berlin, in his inaugural dissertation, was the first to describe certain groups of cells in the pancreas which differed from the ordinary cells of the gland, but whose nature and functions he did not determine. These cell groups or isles are now known as the Islands of Langerhans. It remained for Opie, of Baltimore (1903), to show that if the islands of Langerhans are intact, no sugar appears in the urine. In this connection, however, the English surgeons Mayo, Robson and Moynihan, hold that while extirpation of the whole pancreas produces diabetes in a large number of instances, there may be diabetes without apparent pancreatic disease, and, on the other hand, chronic interstitial pancreatitis without diabetes. Furthermore, the experiments of Ssobelou (1902) are interesting. He destroyed the gland *in situ* (as he thought) in animals, by Claude Bernard's method, but glycosuria did not occur. The query then was, Did he actually destroy the gland in its entirety? If so, some other gland must be competent to act vicariously for the pancreas. Having paid some attention to the subject of fat necrosis, he went on to say that it was difficult to do justice to all the men, indeed, all the Americans, who have aided in the advancement of our knowledge of pancreatic diseases and their treatment. In 1886 Senn, of Chicago, gave a masterly review of the surgery of the pancreas, and laid down rules for operative procedures which

have had wide recognition. In 1889 Lund, of Boston, demonstrated the possibilities of surgery in acute pancreatitis by a successful operation (said to be the fifth successful one), in a case of pancreatic abscess and fat necrosis. In the same year Fitz, of Boston, in his Middleton Goldsmith lecture, delivered in this Academy building a classical paper on pancreatic hemorrhage, and the various forms of acute pancreatitis that brought the subject of pancreatic diseases prominently before the medical profession everywhere. As yet, it is a matter of regret that medical treatment, other than palliative, offers so little hope. Fortunately, however, there is ground for belief that even in the acute form spontaneous cures may take place. Chronic pancreatitis is more amenable to treatment, because the signs are more distinct and there is more time to study them. After the acute symptoms have been relieved by the medical attendant, and surgical intervention has been decided upon, the prognosis for an operation is fairly good. So far as the diagnosis of pancreatic disease is concerned, it is well known that there are many difficulties and many failures, especially in the acute form. It is difficult certainly to contra-distinguish pancreatic disease from peritonitis, interstitial obstruction, cholelithiasis, gastric or gastro-intestinal tumors or ulcers. Still there is no doubt that we are making progress every year.

Advances in the Physiology of the Pancreas and their Application to the Diagnosis of the Diseases of the Pancreas.—Dr. John C. Hemmeter, of the University of Maryland, spoke on this subject. Exact physiological knowledge concerning the functions of the pancreas, he said, dates from the discovery by Claude Bernard, in 1848, that the secretion of this organ is capable of digesting fats. In 1857 Corvisart ascertained that it has the power of digesting proteid material. Having referred in passing to the work of other investigators, he spoke particularly of the epoch-making discoveries of von Mering and Minkowski, who, in 1889, demonstrated that diabetes can be experimentally produced in the dog by extirpating the pancreas, and that the appearance of sugar in the animal's urine is accompanied by all the characteristics of glycosuria, as it occurs in the human being. On the basis of numerous investigations into the pathological histology of the pancreas in cases of diabetes it was established that many cases of this type of disease are due to atrophy, fatty degeneration, and tumors of the pancreas. Degenerations of the islands of Langerhans have been particularly associated with diabetes, but the fact must be emphasized that in some instances of very severe diabetes no changes whatever were demonstrable in the pancreas. Pearce has recently furnished confirmatory evidence from the human embryo that the islands of Langerhans, though originating through a proliferation and differentiation of the cells of the primitive secreting tubules of the pancreas, eventually become wholly independent structures anatomically. On the basis of physiology, histology, pathology and embryology, therefore, the pancreas, as it now appears, represents an organ within an organ—a duplex structure with, first, a function to the interior, and, second, to the exterior, the intestinal canal being practically outside the body proper. The islands of Langerhans, which are not concerned in the elaboration of the pancreatic ferment, are identified with the first, and have been shown to exert an influence upon the carbohydrate metabolism, probably by an internal secretion. The glandular parenchyma, on the other hand, is concerned with an external secretion, the digestive pancreatic juice. It is undoubtedly a fact that none of its functions belongs exclusively to the pancreas, so that all of them are capable of being performed vicariously by other organs (the stomach and intestine). Pearce has laid emphasis on the fact that the cells of the islands of Langerhans give evidence of a remarkable resistance to degenerative processes. This makes it conceivable that we may eventually succeed in destroying the digestive or ferment-producing cells in a living animal and leaving the islands of Langerhans intact. It has occurred to Dr. Hemmeter that possibly this might be produced by the pancreatic juice itself, or by inducing an autolysis of the digestive cells of the pancreas through the influence of its own digestive ferment. In an autopsy on a case of diabetes which had recovered from the symptoms of glycosuria, but had eventually succumbed to consequences of cholelithiasis, he observed a partial autolysis of the glandular apparatus of the pancreas, whereas the islands of Langerhans did not appear to be diseased. At present the diagnosis of pancreatic diseases must depend more upon the clinical data than upon the results of chemical researches in the laboratory. There are three requisites which conservative clinicians should demand of all published assertions concerning the clinical pathology of the pancreas: (1) A concrete and precise account of the objective and subjective signs and symptoms. (2) Quantitative and qualitative chemical analyses of feces, blood and urine after the ingestion of weighed amounts of proteids, carbohydrates and fats, preferably each given alone. (3) Accurate description of the findings that are discoverable either at operation or at autopsy. In conclusion, Dr. Hemmeter stated that his principal aims on this occasion were (*a*) to point out the possibility of separating the islands of Langerhans (concerned in control of carbohydrate metabolism) from the part of the pancreas concerned in the secretion of the digestive juice, and (*b*) to demonstrate that active proteolysis may take place in the intestinal canal in the entire absence of pancreatic secretion.

Experimental Researches.—Dr. Richard M. Pearce, of the Albany Medical College, said that the pancreas lends itself to experiment perhaps more readily than any other organ of the body. Among the researches undertaken have been many to determine the injury caused to it by various irritating substances. These give rise to inflammation characterized by necrosis and to hemorrhagic pancreatitis. It is possible on the present occasion to consider the effects of but four of these irritants. (1) The action of a ferment. It is a question whether it is possible to produce pancreatic hemorrhage (apoplexy) without inflammation. Probably hemorrhagic pancreatitis always results. As to the order of the phenomena, hemorrhage, necrosis and inflammation, Dr. Flexner and himself had endeavored to ascertain which of these occurred first. In their experiments all three were found at the end of one hour, and the conclusion was reached that they occur almost simultaneously. A large number of the cases of pancreatitis are associated with gangrene, but this usually occurs only as a secondary phenomenon at a late stage of the inflammation. Suppuration occupies a position by itself. While hemorrhagic pancreatitis is diffuse, suppuration is distinctly localized (in abscesses). In the hemorrhagic and gangrenous pancreatitis there occurs a form of inflammation different from that met with in other organs, but suppuration in the pancreas is the same as observed elsewhere. Fat necrosis is a common complication of pancreatitis. (2) Action of bacteria. This is apparently secondary. (3) Action of gastric juice. In the experiments artificial gastric juice was employed. In man there is no evidence that irritation by the gastric juice can take

place. (4) The relation of bile to acute pancreatitis. Proof has been furnished that bile entering the pancreatic duct may give rise to hemorrhagic pancreatitis. In the experiments conducted by Dr. Flexner and himself, however, only a very small proportion of cases of cholelithiasis were complicated by pancreatitis. The old classification of pancreatitis by Fitz into hemorrhagic, gangrenous and suppurative, seems to answer all purposes. As all these varieties are accompanied by more or less necrosis, it is hardly necessary to add a fourth variety.

Pathology.—Dr. George P. Müller, of the University of Pennsylvania, described the lesions observed in the acute and chronic forms of pancreatitis and the relation which such lesions bear to the question of diagnosis. Acute pancreatitis, he said, with its fearful rapidity of progress and great mortality, presents but few lesions. They are essentially those of a peritonitis in the upper abdomen, with varying lesions in the gland itself, and often diffused fat necrosis, which may extend to the epiploic appendages of the sigmoid or to the meso-appendix on the right. Destruction of the parenchyma of the pancreas ensues, and one of two types of disease presents itself. Acute hemorrhagic pancreatitis is an affection peculiar to the pancreas and undoubtedly due to the complexity of the ferments and of the internal secretion. The impaction of a gall-stone more nearly explains the sudden onset than any other. The pancreatic secretion, acting upon cells injured by retained ferments, infection, etc., causes areas of necrosis and hemorrhage which may eventually involve the entire gland. An inflammatory reaction, marked by the presence of large numbers of polynuclear leucocytes, is present from the beginning. In microscopical sections of the pancreas the interacinous, interlobular and peripancreatic tissue is seen infiltrated with blood, and the intact blood-vessels distended, with walls swollen and cloudy. The acini, if identified, are barely discernable, their nuclei are lost, and the cells are granular and cloudy in appearance. In various areas the destruction of the gland becomes total, and nothing can be discerned, except a structureless granular débris. In gangrenous pancreatitis, the termination of the acute lesion, the organ is large, friable and slate-brown or purple in color, and upon section presents a mottled red and black appearance, with no visible evidence of any structure, except perhaps the duct of Wirsung. In suppurative pancreatitis, which is due to infection by bacteria, the pus is observed as multiple small abscesses or metastatic deposits, distinguishing this form from the hemorrhagic disease with infiltration and diffusion of the leucocytes into the already formed necrotic tissue. The abscess, if large, may open into the peritoneal cavity—more rarely externally; and, if primary in the pancreas, may infect the portal vein and liver. Fat necrosis is an interesting chemical reaction by which the pancreatic ferment, by virtue of its fat-splitting element, infiltrates the fat in the peritoneal cavity, and induces specks of necrosis followed by the production of the crystalline calcium salts. At the present time the appearance of these scattered white points in the mesentery and omentum, when the abdomen is opened at operation, must be considered as indicating a grave lesion in the pancreas and a probable fatal termination. The peritoneum is variously affected by acute pancreatitis, and sometimes there is present a true and often diffuse peritonitis, especially when the pus in the suppurative form has broken into the peritoneal cavity. Chronic pancreatitis is of immense importance at the present time by reason of the brilliant prospect which surgery offers in the cure of a disease long believed to be incurable, and frequently confused, in diagnosis, with malignant disease. The pancreas parallels the liver in a fairly close manner when attacked by chronic indurative inflammation, though the lesions observed have a more direct bearing upon the clinical findings. Having spoken of the etiology and microscopical appearances, Dr. Müller described a case in which pancreatic calculi completely obstructed the duct of Wirsung and the gland was in a state of complete atrophy. Pancreatic calculi, he said, have rarely been diagnosed during life, and only once has such diagnosis been followed by operation. As a result of the obstruction of the pancreatic ducts by the calculi, the parenchyma suffers, an interlobular pancreatitis occurs, and atrophy of the gland is the result.

Classification and Symptomatology.—Dr. Charles G. Stockton, of the University of Buffalo, said that the classification of diseases of the pancreas was especially difficult, partly because of the incompleteness of our knowledge of the pathology and partly because the pancreas secretes certain enzymes or other active principles which, in the presence of disease, lead to peculiar and remarkable changes, both in function and structure. Tumors of the pancreas occur, as carcinoma of various kinds, adenomata, tuberculosis, syphilis, and cysts, the last presenting at least three varieties: retention cysts, proliferation cysts, and hemorrhagic cysts. Chronic pancreatitis is usually described as induration, although fatty degeneration and fatty ingrowth often form a considerable part of the mass. We have come to accept two forms of distribution of the fibroid degeneration, one the ordinary interlobular type, the other characterized by diffuse proliferation of the interasinar tissues, which invades the islands of Langerhans and apparently constitutes the structural change upon which pancreatic diabetes depends. When the induration involves the head of the pancreas it may, from pressure, obstruct the common bile duct and give rise to phenomena, which suggest malignant growth or cholelithiasis. If the choledochus escapes, there may still ensue symptoms of more or less importance, depending upon interruption of the pancreatic function. These are glycosuria (persistent if the disease invades the islands of Langerhans), the signs of interstitial indigestion, and, occasionally, fatty stools, lipuria, sialorrhea, emaciation, and, it may be, severe anemia. Given a palpable induration in the region of the pancreas and disturbance of intestinal digestion, with, at times, traces of sugar and albumin in the urine, with or without increased salivation, fatty stools, or lipuria, and depreciation in general health, without the cachexia of cancer, then one may make a provisional diagnosis of chronic indurative pancreatitis. Having referred to the classification of inflammatory diseases of the pancreas given by various authors, he said it did not seem to be satisfactory to attempt the explanation of acute pancreatic processes along the line of ordinary inflammation. In some instances an inflammatory reaction is evident; in others it is entirely lacking. What is present in all cases is the escape of pancreatic secretion into the tissue and the consequent necrosis of the pancreas and surrounding parts, accompanied by hemorrhage, liquefaction necrosis, and fat necrosis. While it is admitted that these phenomena may be excited by an inflammation of the organ, the fact must not be lost sight of that there are cases free from infection, and therefore inflammation, as that term is used at the present day. In the so-called hemorrhagic pancreatitis no pus whatever is found, but suppurative pancreatitis, due to infection, follows a different course. The symptomatology of acute hemorrhagic pancreatitis and that of hemorrhage into the pancreas are very closely related. In the onset there are intense pain in the lower part of

the epigastrium, manifestations of shock, and generally nausea and vomiting. These symptoms may continue for a few hours or days, and then subside. Not infrequently the pain diminishes, but the prostration continues, vomiting recurs, and the temperature is raised from one to three degrees. The abdomen is slightly distended, and there is increased resistance in its upper half, where there is also more or less marked tenderness. The bowels are usually somewhat sluggish, but lack the motor paresis of peritonitis. The symptoms are increased by movements of the body, and yet there is not the disinclination to change position observed in cases of peritonitis. In a few instances slight transient glycosuria appears, and traces of albumin in the urine are to be expected. Patients may continue in this condition for several days, or even weeks, and spontaneous recovery may possibly occur. More often the process continues for a few days without marked change, when somewhat suddenly the prostration increases, the pulse becomes almost imperceptible, and death results apparently from abdominal shock. When suppuration is associated with hemorrhagic pancreatitis, we find added to the symptoms of the latter those of septicemia. In other cases of suppurative pancreatitis the manifestations are often merely those of suppuration in the upper part of the abdomen, and the element of shock may be less marked than in the hemorrhagic form of the disease. Leucocytosis is to be expected in suppurative cases, but is inconspicuous or absent in those of other types. Fat necrosis occurs in most, but not all, acute processes of the pancreas, whether suppurative, necrotic or inflammatory.

Prophylaxis and Medical Treatment.—Dr. Glentworth R. Butler read a paper on this branch ot the subject. This paper will appear in full in a subsequent issue of the Medical News.

Surgical Treatment of Pancreatitis.—Dr. John B. Deaver, of Philadelphia, said that the indications for operation in acute pancreatitis are furnished by the pathology of the disease and the history of the cases so far reported. The extraordinary rapidity with which death so often follows, shortly after the onset, makes any delay inadvisable; and yet, the diagnosis is so difficult and the symptoms are so ill-defined that the mortality following operation is very high. In many forms of acute pancreatitis the disease appears to be a destructive infiltration of tissues by ferment, often associated with infection, and only in those cases where local areas of pus produce necrotic foci does it limit itself. For this reason he believed that the early operation, rationally conducted, as Mikulicz expresses it, will finally give us the better results. The technic of such an operation varies with the condition present. Upon opening the abdomen, fat necrosis, if present, is a symptom of great moment, and, of course, decides the diagnosis. The gall-bladder should be palpated for calculi, and the common duct explored with the finger. The intestines and surrounding viscera must be protected by gauze pads with great care. The pancreas may be reached (1) through the gastrocolic omentum, below the stomach; (2) through the gastrohepatic omentum, above the stomach, or (3) through the transverse mesocolon, back of the colon and stomach. The first method is the most applicable for the purpose of drainage. Having cited certain points formulated by Mikulicz, he said that the bleeding in hemorrhagic pancreatitis was often hard to check, and might require the extensive use of gauze tampons or even the introduction of sutures. The latter was to be avoided, if possible. Progressive necrosis of the pancreatic cells from the action of the ferment, while not to be checked by operation, may be prevented to a great extent by free drainage. Infections from the duodenum involving the pancreas require the usual treatment for infected areas elsewhere, free incision and drainage. If the pancreas merely presents a swollen, tense, edematous appearance, and there is no marked peripancreatic involvement, an incision should be made in the long axis of the organ, extending its entire length, if necessary. Drainage to this opening, though uphill, will sufficiently provide for the serous effusion and broken-down products. When the peripancreatic involvement is severe, loin drainage is required, after free incision of the pancreas. Abscess, necrosis, and gangrene of the organ require identical treatment. Before completing the toilet of the abdomen the area of disease should be carefully walled off from the general peritoneal cavity by gauze. In cases in which the presence of stones in the gall-bladder or bile ducts is discovered the operation is considerably complicated, as the incision is too far to the left for the best performance of cholecystostomy. The surgery of chronic pancreatitis has been made in recent years. After alluding to the work of Senn, published in 1886, Dr. Deaver said it was principally to Mayo Robson that we owe the impetus given to the surgical treatment of chronic inflammatory enlargements of the head of the pancreas. He then gave a résumé of the essential lesions of chronic disease from the standpoint of surgery, and went on to say that the cause of the disease must be removed, if a biliary or pancreatic stone, and temporary or permanent drainage of the bile provided for. Most surgeons prefer the external opening, or cholecystostomy, and the great advantage of the latter method is the ability to keep the drainage under constant observation. When the stone is located as being in the ampulla of Vater, it is best to open the duodenum and slit up the papillæ, such a procedure not requiring any suture to reclose the duct. A choledochotomy is required if the calculus is in some other position. Pancreatitis without stone is frequently completely relieved by a simple cholecystostomy. When there is glycosuria without obstruction of the biliary apparatus, great relief may be afforded by a cholecystostomy, but theoretically an operation offers no hope for cure, as the diseased islands of Langerhans are not dependent on any lesion ascending through the ducts. In cases with obstruction of the pancreatic duct by a calculus the operation required depends upon the location of the latter, and while it may be reached by opening the papillæ and duct through the duodenum, the operator must be prepared to open the lesser peritoneal cavity and cut down through the gland itself. The operative procedure in pancreatic cysts will depend upon the degree of adhesion to surrounding structures. In only a small proportion of cases can the cyst be dissected out. Aspiration of the cyst should be performed only when the patient is severely ill from diabetes or the effects of pressure. Whenever practicable, the abdomen should be opened by a median incision above the umbilicus, and through either the gastrocolic omentum or the transverse mesocolon; after which the contents of the cyst should be withdrawn by an aspirator, the puncture being closed with one or more hemostats, as the needle is removed. The cyst wall is then drawn to the wound, sutured to the parietal peritoneum, and drained. When the cyst is small and cannot be brought to the abdominal wound, a rubber drainage-tube should be introduced into the cyst cavity, surrounded by gauze packing to prevent leakage.

Dr. Howard C. Russell, of the United States Marine Hospital Service died Wednesday at the Marine Hospital, at Stapleton, S. I., from pneumonia. He was born at Washington, D. C., and was educated and obtained his medical degree at the University of Pennsylvania. He was appointed to the Marine Hospital Service on July 1, 1897.

BOOK REVIEWS.

The Prevention of Consumption. By Alfred Hillier, M.D., C.M., B.A., Secretary to the National Association for the Prevention of Consumption (London), etc. Revised by Professor R. Koch. Longmans, Green & Co., London, New York and Bombay.

In his introduction to Dr. Hillier's book Professor Koch says: "In all respects it represents the latest scientific views, which are so clearly expounded that every intelligent reader can derive reliable instruction from them. A special merit of the author is that in dealing with points still matters of controversy in the science of tuberculosis he handles them with such skill that the true value of varying opinions is shown." This is high praise from the best authority. We think that readers of the book will find it not undeserved. Nowhere else can one find crowded into 200 small pages so much that is practical and thoroughly up to date with regard to tuberculosis. The compression necessary has been accomplished with special success, though we think that it might have been longer as regards certain details of prophylaxis, with addition to its value.

The Self-cure of Consumption Without Medicine. With a Chapter on the Prevention of Consumption and Other Diseases. By Charles H. Stanley Davis, M.D., Ph.D. Member of the Connecticut State Medical Society, etc. E. B. Treat & Co., New York.

We have one fault to find with this little book, valuable in other ways, and that is a fault common to a number of recent publications with regard to tuberculosis. It appears to make the cure of consumption almost too easy, and there is apt to be the feeling created among incipient consumptives that after all they are not suffering from a very serious condition. This may easily lead to neglect of the rather severe regimen that any consumptive must accustom himself to carry out if he is going to obtain a cure of his disease. Otherwise the book contains many valuable hints put in a very practical way.

The Pathogenic Microbes. By M. Le Dr. P. Jousset, Physician to the Hospital St. Jacques, Paris. Authorized translation by Horace P. Holmes, M.D. Boericke & Tafel, Philadelphia.

We scarcely see any reason why this little book should have been translated into English. We have a number of volumes by American authors that cover just the same ground and seem to be quite as well done. Dr. Jousset's book is a good little hand-book as compends go. It is scarcely more than this. We venture to say that there are at least half a dozen volumes almost as compendious and quite as valuable otherwise as this.

The Blues (Splanchnic Neurasthenia). Causes and Cure. By Albert Abrams, A.M., M.D. (Heidelberg). F.R.M.S. Consulting Physician Denver National Hospital for Consumptives, etc. E. B. Treat & Co., New York.

Dr. Abrams' little book of nearly 250 pages gives an excellent idea of some of the varying phases of the neurotic conditions popularly termed "the blues." In the summary of his first chapter he says that "an attack of the blues is an attack of acute neurasthenia or an aperiodic aggravation of chronic nervousness. Heredity may be responsible for the susceptible nervous system, and it devolves on the individual to obey the laws of hygiene and to avail himself of momentary advantages, however minute, to withstand the effects of conditions which either weaken or improve the status of his vitality."

There are a number of very practical points with regard to the varying phases of the disease, and the various chapters are summarized very interestingly. The book would well stand more condensation, but still is worth reading, especially for those who have much to do with the idle rich, with so much time on their hands that the blues become a frequent source of annoyance.

Manual of Medicine. By Thomas Kirkpatrick Monro, M.A., M.D. Fellow of and Examiner to the Faculty of Physicians and Surgeons, Glasgow, etc. W. B. Saunders & Co., Philadelphia and New York.

This work has at least the distinctive character sometimes missed in text-books on medicine of giving due credit to the men to whom the author is indebted for much help in the compilation of his book. As Americans we are pleased to find in conjunction in his expressions of indebtedness such names as Sir William Gowers, Sir William Broadbent, Dr. Sansom and our own Professor Osler. Altogether the book contains some 900 pages, and will undoubtedly be useful to students. The author hopes also that it will be of service to junior practitioners. Personally we should be very much better pleased if both students and junior practitioners of medicine early acquired the habit of consulting some more extensive standard work well known as an authority on various subjects, which would eventually become a companion with a definite place in local memory for problems previously solved by means of it. We think that this book is as good as any can be made with such condensation as is necessary under these circumstances, though we are inclined to deprecate the making of many manuals which must find a place somewhere between the compend intended merely to help the student's memory and the text-book, which should become a familiar and loving companion.

The Hospital Formulary of the Department of Public Charities and the Department of Bellevue and Allied Hospitals of the City of New York. Sixth Revised Edition. W. E. Dreyfus, A.B., Ph.D., Editor, New York.

This volume, very substantially bound in leather, constitutes an important addition to any physician's working library. As much as possible formulæ of a similar nature have been brought together, so as to avoid the necessity for frequent reference to the index. An addition special to this revision is an index of diseases for which the formulæ are usually employed. This will undoubtedly prove, as the chemist of the Department of Public Charities suggests, a valuable feature for younger physicians at least. The book is an excellent sample of the sort of work that has been done in the last few years in the Department of Public Charities, and the preface closes with the request for notifications as to alterations or additions desired in future additions, that shows a commendable willingness to make the formulary even more valuable, if possible, in the future.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, etc. By Leading Members of the Medical Profession Throughout the World. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia, U. S. A. With Regular Correspondents in Montreal, London, Paris, Berlin, Vienna, Leipsig, Brussels and Carlsbad. Volume 4, Thirteenth Series. J. B. Lippincott Company, Philadelphia.

The present volume of the International Clinics, which closes the first year under the new editorship, shows that the improvement manifested in the character of the contents of the Quarterly has been continued.

Perhaps there is to be noted, however, a tendency to overspecialization, which will deter the general practitioner readers of the periodical. There are excellent medical articles, however, on the Importance for Students of Physiognomical Diagnosis in Disease, by Sir Dyce Duckworth, of London; on Some Clinical Aspects of Diseases of the Kidneys, by Henry Baird Favill, of Chicago; and on The Parallelism Between the Clinical Symptoms and the Pathological Lesions of Rheumatic Fever, by F. J. Poynton, of London.

Very timely articles on treatment are those on the Treatment of Croupous Pneumonia, by John H. Musser, of Philadelphia, and the Treatment of Chronic Bronchitis, by Thomas A. Claytor, of Washington. Dr. Musser insists especially on the individualization of treatment, though he gives many precise practical directions and various drugs that may be employed with advantage in the treatment of this disease. For those who wish to realize the present state of medical knowledge regarding the subcutaneous use of mercury in the treatment of syphilis, Professor Julien, of Paris, has written an excellent review, historical and evolutionary, of this use of mercury. There is much more in it than is usually supposed by those who have been accustomed to prescribe mercury only by the mouth, and in the severer cases, especially this form of treatment, it would seem, must be ready at hand if the medical practitioner would do his whole duty by his patients.

Nineteenth Annual Report of the Bureau of Animal Industry, United States Department of Agriculture, for the year 1902. Government Printing Office, Washington.

This annual report always contains some material interesting to physicians and especially to bacteriologists. In the present volume there are articles on scabies in cattle, the duration of the life of the tubercle bacillus in cheese; statistics of oleomargarine, oleo oil and filled cheese; bovine tuberculosis and other animal diseases affecting the public health; foot and mouth disease, Voges' description of *mal de caderas*, a South African trypanosomatic disease of domestic animals; contagious diseases of animals in foreign countries, and a report on the tuberculin test of cattle in Great Britain. As these articles are written by such experts as D. E. Salmon, Charles Wardell Stiles, R. W. Hickman, there is no doubt that the details presented can be absolutely depended on and they may prove of value in the study of analogous diseases in human beings.

Compend of Pathology, General and Special, a Student's Manual in one volume. By Alfred Edward Thayer, M.D., Professor of Pathology, University of Texas. Second Edition. P. Blakiston's Son & Co., Philadelphia.

In his preface Dr. Thayer says that the two compends of pathology issued by him in 1902 are here presented in a second edition as one volume. A special chapter on the nervous system has been added and the text thoroughly revised. The book is meant for students and is certainly a handy volume, containing a great deal of valuable material in its seven hundred odd pages. It is, however, beyond the range of a compend and yet scarcely a textbook. It is not easy to understand the position that it will occupy in medical literature except as a book for students to have and consult for examination and recitation purposes, which in later editions will become a full-fledged text-book. It seems almost too bad that students should not become familiar during their college days with some classical complete text-book, rather than a makeshift meant only for the passing years of school life.

Mammalian Anatomy. With Special Reference to the Cat. By Alvin Davison, Ph.D., Ex-Fellow of Princeton University; Professor of Biology in Lafayette College. P. Blakiston's Son & Co., Philadelphia.

This little book is an excellent compendium of mammalian anatomy as it can best be studied outside of medical schools. The cat has frequently been used as a type of the mammal and this guide seems to be concise yet complete and very well illustrated. The compression has been especially well done, for in spite of brevity there is very little that is important in mammalian anatomy that is not to be found within its covers. The harmless, necessary cat makes an excellent substitute for the higher mammal and the opportunities afforded by its structure have been well taken advantage of.

Annual Report of the Health of the Imperial Navy for the Year, 1901. Tokyo.

If the present volume is an index of the administrative control existing throughout the Japanese navy there is no reason to believe that this department of the Mikado's fighting force is less intelligently or efficiently organized than that of any other world power. This report is a model of its kind and presents the health statistics of the imperial navy tabulated from every conceivable point of view. The mean daily force of the service for the year 1901 was 26,469 and the number of patients treated for the year was 24,870, which is in the ratio of 942.76 per 1,000 of force. As this figure shows a decrease of 36.63 per 1,000 over the preceding year the "chief of Bureau of Medical Affairs," Baron Saneyoshi, F.R.C.S., Eng., H.M., is no doubt pleased with the work of his staff.

The Treatment of Neurasthenia. By A. Proust, Professor in the Faculty of Medicine of the University of Paris, and Gilbert Ballet, Professor Agrege of the Faculty of Medicine of Paris. Translated by Peter Campbell Smith, Laureate of the Royal College of Physicians of Edinburgh. Edward R. Pelton, New York.

This little book is a very popular manual of the treatment of the hydra-headed symptom complex of neurasthenia, as formulated in France. It has been before the American medical public for some time and has deservedly gained a reputation for itself, for its thoroughly practical character. The chapter on the prophylaxis of neurasthenia is the best in the book. The chapter on moral education, particularly, will be helpful to those who want to prevent neurotic growing children from becoming adult neurasthenics. The concluding chapters on neurasthenia in women and genital neurasthenia are excellent compends of difficult subjects.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

A Handbook on the Prevention of Tuberculosis. Published by the Charity Organization Society of the City of New York. 8vo, 388 pages. Illustrated. New York.

Non-Surgical Treatise on Diseases of the Prostate Gland and Adnexa. By Dr. G. W. Overall. 8vo, 205 pages. Illustrated. Marsh & Grant Co., Chicago.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 84. NEW YORK, SATURDAY, MARCH 12, 1904. NO. 11.

ORIGINAL ARTICLES.

A CLINICAL STUDY OF SIXTY-TWO CASES OF INTESTINAL INFECTION BY THE BACILLUS DYSENTERIÆ (SHIGA) IN INFANTS.*

BY LINNÆUS EDFORD LA FÉTRA, M.D.,

OF NEW YORK;

INSTRUCTOR IN DISEASES OF CHILDREN, COLUMBIA UNIVERSITY; ASSISTANT ATTENDING PHYSICIAN TO THE BABIES' HOSPITAL, ETC.;

AND

JOHN HOWLAND, M.D.,

OF NEW YORK;

PATHOLOGIST TO THE FOUNDLING HOSPITAL; ATTENDING PHYSICIAN TO WILLARD PARKER HOSPITAL; ASSISTANT ATTENDING PHYSICIAN TO ST. VINCENT'S HOSPITAL.

IT is necessary to emphasize at the outset that this study is entirely clinical. The *Bacillus dysenteriæ*, first proved to be the cause of Japanese dysentery by Shiga, and later to be responsible for the disease in Manila, the United States, Germany and other countries, is now universally regarded as one of the etiological factors in adult dysentery.

Duval and Bassett in 1902, working under Flexner's direction, isolated the bacillus of Shiga from the stools of infants suffering from summer diarrhea. Their results have been confirmed by many other investigators, and infection with the *Bacillus dysenteriæ* is now believed to be the rule in a large proportion of all forms of the diarrheas of infancy, both in the winter and in the summer.

It is not our intention to discuss the cause of diarrhea in infants, or the bacteriology or pathology of this condition. This clinical study was a part of the investigation carried on during the past summer by the Rockefeller Institute for Medical Research and was intended to deal with the symptoms observed in those patients in whose stools the *Bacillus dysenteriæ* was found.

The cases that make up the material for this study were all observed by the writers at the Vanderbilt Clinic during the months of July, August and September, 1903. The patients were brought to the dispensary, which is an outpatient service, and the milder cases were seen only every alternate day. The severe cases were, in addition, visited and treated at their homes on the days that they did not come to the clinic by Drs. Peter Irving and Frank Erdwurm, whose efficient cooperation made full reports possible. To insure uniform records use was made of printed blanks upon which could be recorded the history, physical examination and daily observation of each case. The form of blank chart used is shown on page 482.

When a child was brought with a history of diarrhea, effort was made at the time of the first visit to obtain a fresh stool for immediate bacteriological examination. By using the thermometer by rectum or inserting a suppository it was possible in most cases to obtain a stool. The stool was passed into a sterile piece of unbleached cotton, then taken at once to the bacteriologists, Drs. Duval and Schorer, working in the same building. In forty-eight hours a bacteriological report on the presence or absence of the dysentery bacillus could be obtained.

At first only those cases were examined bacteriologically that gave the history or presented symptoms of a moderately severe diarrhea; but later, on account of the numerous positive findings, all cases of mild diarrhea and intestinal indigestion were also examined. This makes our report of far greater interest, our cases being successive ones, no selection at all having been attempted after the first four cases; while other cases that have been published up to this time have been those selected for their severity, or for some reason regarded as suitable and likely to contain the bacillus of dysentery. One small series examined seriatim has been reported. Comment upon these cases will be made later.

Some patients were seen but once; in others, though seen several times, the result of the disease was unknown. Undoubtedly some of these cases recovered so that they were not brought back to the clinic; others refused to return after the first injection of the serum.

As routine measures, cow's milk was immediately discontinued and not resumed for several days; in breast-fed infants the nursing was forbidden for a time. Barley water, rice water or broth was substituted for the milk. Free catharsis was obtained by means of calomel and castor oil. Other drugs were rarely used.

There were in all 62 cases of infection with the *Bacillus dysenteriæ* (Shiga); of these 2 were observed during June, 33 in July, 18 in August and 9 in September. The investigation was begun late in June and ended September 15, so that only during July and August were observations carried throughout the whole of the month; hence, the small number of cases reported in the first and last months, June and September, has little significance.

Age.—Eight of the patients were under three months; 14 were between three and six months; 15 were between six and nine months; 9 were between nine and twelve months, and 15 were over one year, and of 1 the age was not stated.

Of the 8 patients under three months of age, 5 were only slightly sick; 1 moderately, and 2 severely sick.

Of the 14 patients between three and six months 7 were mild infections; 4 moderately severe; 2 severe, and 1 patient was only seen once.

Of the 15 between six and nine months 3 were

* From the Rockefeller Institute for Medical Research, and the Vanderbilt Clinic, New York City.

mild cases; 9 were moderately severe, and 3 severe.

Of the 9 between nine and twelve months 5 were moderately severe and 4 severe cases.

Of the 15 over twelve months, 1 was a mild case; 11 were moderate cases and 3 severe cases.

From an analysis of these cases it would appear that the number of moderately severe and severe cases increases proportionately with the increase in age. This is explained, however, by the fact that a majority of the mild cases under six months of age in this series were breast-fed.

Previous Illness.—An attempt was made to learn if the patient had previously suffered from diarrhea and by reason of this was more susceptible to infection with the *Bacillus dysenteriæ*. The statements were so unreliable that no conclusions could be drawn. No other predisposing cause in the way of disease could be discovered.

Symptoms had existed for 5-10 days in 17 cases

FACSIMILE OF HISTORY CHART.

Character of Food.—Of the 14 severe cases, 1 was breast-fed; 5 were given condensed milk; 2 Straus' sterilized milk; 2 grocer's milk; 3 fairly clean bottled milk, and 1 case not stated.

There were 14 children entirely breast-fed, 2 children were partly breast-fed; 11 children had been fed on grocery milk; 7 on bottled milk of fair quality; 8 were fed partly or wholly on sweetened or unsweetened condensed mink; 5 on proprietary foods without milk; 2 on Straus' sterilized milk; 2 on home sterilized milk; 1 on peptonized milk; 4 on general diet and no statement in regard to 7 (counted twice 1).

emaciated, weak and in wretched condition; 2 were in collapse and practically moribund on the first examination.

It is most interesting and instructive to notice in this connection that of the 31 children who were well nourished, 14 had a very mild form of disease, 12 were moderately ill and only 5 severely ill; of the 2 fairly nourished, 1 was very slightly and the other severely ill; of the 11 poorly nourished, 7 were moderately, 3 severely and only 1 slightly ill. Of the 13 emaciated, 3 were severely ill, 10 moderately, and not one had the disease in a mild form. From this it would seem that the most important factor in determining the character and severity of the disease is the previous condition of the child.

Of the cases observed by us 16 were very mild, 31 were moderately severe and 14 were severe; 1 case was lost sight of and so was unclassified.

We characterized as mild those cases that had more frequent passages than normal, but not more than 10 a day, with a temperature of less than 100.5° F. These stools contained undigested food, usually mucus but no blood (such cases were not really sick). Those cases were classified as moderate that had a temperature over 100.5° F. or had frequent passages containing mucus and sometimes, a slight amount of blood. These cases were really sick and showed constitutional symptoms. The severe cases comprised those having marked constitutional symptoms and great depression with frequent mucous stools, often with much blood, and, while the temperature in these cases was usually considerably elevated, many of them and some of the most severe ran an almost afebrile course.

Thirty-four cases did not show a temperature of over 100.5° F. and thus more than one-half of those seen by us were practically without fever. Vomiting occurred in 19 cases, usually at the beginning of the attack.

The number of stools in twenty-four hours was from 2 to 5 in 5 cases; from 5 to 10 in 35 cases; and over 10 in 20 cases. In 2 cases the number was not stated.

Two cases had stools without any mucus; mucus was present in all other cases in varying quantity from a minute amount to practically the whole stool. Blood was present in 17 cases; the quantity of blood varied from a few streaks to enough to color all the mucus; no clots of blood were ever observed.

The following cases are cited as representing *types of the different degrees of severity*:

Mild (*breast-fed infant*), P. B., five months old, nursed entirely, every three hours. Had never been ill and his condition at the beginning of the attack was good. His illness began two days previously with three green mucous stools per day. No fever, no vomiting, no blood in the stools. Physical examination was negative. He was rather restless, but otherwise seemed perfectly well and had a temperature of only 100° F. The stool seen at the dispensary was green, moderately large, semi-liquid with mucus, no blood. Breast-feeding was ordered discontinued and barley water feedings substituted; small doses of calomel were given. The following day the condition was the same, character of stools unchanged and the same number. On the next day the stools were two in number, yellow, fecal, with only a little mucus and everything seemed so satisfactory that breast-feeding was resumed with an absolutely uninterrupted convalescence.

Such a case would formerly have been considered a very mild case of intestinal indigestion; but the bacteriological examination showed the presence of the acid producing* type of dysentery organism.

Mild (*bottle-fed infant*), W. P., six months old, in good general condition. Never had the breast, bottle-fed from birth; at present being fed a mixture of malted milk 3 teaspoonfuls, and water 1 pint; of this 5 ounces were given every two or three hours. Illness began three days previously with loose, mucous stools, averaging ten a day, no blood, no vomiting. Temperature 100.5° F. Did not seem ill. Acid type of organism cultivated from stools. Patient was under observation six days. Child was given calomel, and shortly afterward a dilute milk modification. After treatment was begun the stools were never more than four a day, were yellow and fecal but had mucus and a few curds. These disappeared and the child was discharged entirely well.

Moderately severe, R. W., five months old. Was nursed for four months, afterwards fed on three parts Straus' milk and two parts barley water, taking only 15 ounces of the mixture in twenty-four hours. The baby was in good general condition when taken sick two weeks before being brought to clinic; the onset had been with vomiting and fever; there had been much loss of flesh and baby was markedly prostrated when first seen. The stools were five to seven a day, large, green with considerable mucus and some blood. Temperature 100° to 101° F. The acid type of organism was cultivated from the stools. The patient was under observation nine days; was given calomel and the milk was stopped two days; then a weak milk modification given. The stools became less frequent, their character improved, and on the last day seen were only two in number, yellow and with some mucus. The temperature was normal.

Severe, M. K., seven months. Had been under observation for six months, at the beginning of which time he weighed 4 pounds 15 ounces. Had been fed on various milk modifications and had gained very well; at the time of the attack was of fair weight and in good general condition. For about ten days had suffered from symptoms of intestinal indigestion. The stools were yellow, frothy, and large, and there were ten to twelve in twenty-four hours. There was some tenesmus and mucus in great amount; no blood. Free catharsis and the substitution of barley water for the milk had no effect; stools were still frequent and yellow, and once contained a little blood. The true Shiga type of organism was found by culture from the stools. The temperature was always low never going above 100.4° F. Imperial Granum was no better borne than the barley. The child constantly failed and the stools were still frequent, as many as sixteen in a day; bismuth only colored the stools. In a week the child was in desperate straits, eyes sunken, fontanel depressed and pulse imperceptible. He was given 20 c.c. of Shiga serum in the buttocks on two successive days. Stimulation by whisky and strychnine and hot baths was resorted to. Child was also given a milk and water mixture, 1 to 6. Very decided improvement was seen almost immediately, the number of stools diminishing in one day from sixteen to four; this was three days after the first injection of serum. From this time convalescence

* The acid producing type, *i.e.*, the one that splits mannite with the formation of acid, is also known as the Flexner-Manila or "Harris" organism. The other type that does not split mannite is known as the true Shiga or alkaline organism.

was rapid and three months after the attack he is a fat, well-nourished child, taking milk well and digesting it.

Fatal Cases.—To our knowledge there were 4 fatal cases. It is possible that some others of our cases died, but not while under observation, nor were any in a moribund condition when last seen.

1. J. C., ten months old, in poor condition and emaciated; living in a tenement in fair surroundings, but badly cared for; was taken with diarrhea while being fed on a weak barley water and milk mixture. No history of previous illness, and he had been bottle-fed for eight months. The onset was without vomiting, but with moderate fever and with frequent mucous stools, eight a day, no blood. When first seen on the second day of the attack the baby was markedly anemic; fontanel depressed; heart very feeble; circulation poor; extremities cold; no distention. Lungs negative. Very restless. Milk stopped and barley water given and white of egg with whisky. Temperature 101.8° F. Stools were small and green mucopurulent with streaks of blood. Following day child was extremely prostrated, temperature 101° F.; edema of face and lower extremities; respiration shallow, radial pulse imperceptible. Death thirty-six hours later. The true Shiga type of the dysentery organism was separated from the stools on the first day of observation.

2. G. H., ten months old, in fair condition, living in a filthy tenement, with little sunlight and poor care; was taken sick while being fed a condensed milk mixture. He had been nursed until three months old. The onset was acute by vomiting, high fever, 103.5° F., and diarrhea; stools were six to seven a day and contained mucus, no blood. When first seen, four days after the beginning of the attack, the child was somewhat emaciated; fontanel not sunken; temperature 103° F.; very restless and with some tenesmus. Put on barley water and following catharsis was given a bismuth mixture. On the seventh day of the attack was given 10 c.c. of Harris serum, and these injections were repeated on the eighth and ninth days. By the fourteenth day the general condition was somewhat improved, the temperature having fallen to 100° F., pulse still rapid. The diarrhea had much diminished so that there were only two or there yellow fecal stools a day. A weak milk mixture was given with no bad effect upon the intestinal condition, but the child gradually failed, and in spite of stimulation by whisky and strychnine the extremities became cold; edema came on and the heart gradually gave out four weeks after the beginning of his attack. The mother was densely ignorant and failed to carry out directions, especially in regard to feeding; moreover, she refused to have the child admitted to a hospital. The "Harris" or acid type of organism was separated from the stools on the first day of observation.

3. A. K., three months old, fairly nourished, living in a clean tenement but with little care. Had been nursed entirely for one month. Was taken sick while being fed on Straus' sterilized milk. The onset was sudden with fever and diarrhea, no vomiting. Stools were mucous but contained no blood, twelve a day; there was much tenesmus. First seen seven days after the beginning of the attack; the child was anemic and in collapse. Fontanel depressed. Heart normal; lungs—fine râles at both bases behind. Child was admitted to the Babies' Hospital four days later and was given, with other treatment, 10 c.c. of Harris serum. Refused food and later regurgitated after feeding. Temperature remained between 103° and 105° F., and the child died forty-eight hours later. The stools had diminished to four a day. The "Harris" or acid type of organism was separated from the stools on the first day of observation.

4. M. McK., seven weeks old, a poorly nourished child, living in a dirty tenement with very poor care. Was taken sick while being fed on condensed milk and a proprietary food. The baby had been nursed for three weeks, but nursing had then been stopped because the mother developed an abscess of the breast. The onset was acute with vomiting, but no fever. The stools were five to seven in twenty-four hours; green, mucous and offensive, but contained no blood. When first seen, seven days after the beginning of the attack, the child was much prostrated and anemic, temperature 100° F., and pulse 100 and weak, cold extremities and restless. After catharsis was fed on barley water, stools remained the same; refused food and in spite of stimulation and 10 c.c. of "Harris" serum the baby died four days later after having been in collapse for twenty-four hours.

Of the fatal cases all were under one year of age; all were artificially fed and were in very poor condition when first observed; in addition, they had only the poorest care and attention.

Breast-fed Cases.—There were fourteen infants exclusively breast-fed that suffered from infection with the *Bacillus dysenteriæ*.

1. L. P., six weeks old, good general condition. Stools four to eight a day, watery, with slight amount of mucus, no blood. Five days after the beginning of the attack cathartics were given and barley water was substituted for nursing; in twenty-four hours stools became fecal and the mucus disappeared. Never any vomiting or fever. The acid type of organism was isolated.

2. F. A., six weeks old, good general condition. Diarrhea and vomiting. Stools soft and yellow with some mucus, seven in twenty-four hours. Seen only once. The acid type of organism was isolated.

3. P. B., five months old, good general condition. Onset without vomiting or fever. Three green mucous stools daily. After calomel and withholding the breast the stools became yellow and fecal, two a day, and on the third day of treatment and the fifth of the disease the child was discharged perfectly well. The acid type of organism was obtained from the stools.

4. C. F., two and one-half months old, in good condition at the beginning of the attack. Onset

with high fever, very frequent green, fluid stools with curds and much mucus, no blood, fifteen a day. Temperature 104° F. The acid type of organism found. Referred to hospital but did not go. Seen only once.

5. D. M., four months old, in good general condition; three to five green and mucous stools, no blood; diarrhea began two days before coming under observation. No vomiting or fever; child not at all sick, but the stools contained a little undigested milk and were green for four or five days. On the fourth and fifth days of treatment 10 c.c. of Shiga serum injected. Two days after this the stools became yellow and fecal and the breast-feeding, temporarily withheld, was resumed. The true Shiga bacilli were found in the stools.

6. N. H., eight weeks old, good general condition. Diarrhea with six to eight fluid, mucous stools had begun two days before coming under observation. No fever or vomiting. Castor oil and barley water were followed by prompt recovery in two days. The acid type of organism was found.

7. W. R., eight weeks old, in good general condition. Diarrhea with fluid, mucous stools began without fever or vomiting two days before coming under observation. The exhibition of castor oil and barley water was followed by recovery on the fifth day of the attack. True Shiga organisms found in stools.

8. C. J., three months old, in good general condition. Diarrhea began without fever or vomiting, three days before coming under observation; stools eight to ten, fluid and mucous, no blood. Castor oil and barley water effected a rapid cure in two days. The acid type of organism was isolated.

9. L. G., thirteen months old, fair general condition. Onset acute with fever one week before coming under observation, no vomiting. Stools had been six to eight a day fluid and mucous, no blood, and child had lost much weight. Temperature 101.8° F. Calomel and barley water given. Case seen only once. The acid type of organism was isolated.

10. J. D., one year old, good general condition. The attack of diarrhea began with vomiting and fever; stools four to nine in twenty-four hours, loose, mucous, with slight amount of blood. When seen one week after beginning of attack, temperature was 101° F. Child was somewhat prostrated and emaciated. Tenesmus and prolapse of rectum. Under treatment by castor oil and bismuth, the child improved rapidly.

11. L. A., ten weeks old, excellent general condition, had been sick for one week with diarrhea, five to six yellow, slightly mucous stools daily; no blood, no fever, no vomiting. Calomel and barley water effected a cure in two days, the stools being normal in twenty-four hours. The true Shiga and the acid type of organism were both present.

12. R. A., five months old, good general condition. Diarrhea, six to eight fluid mucous stools without blood. No vomiting or fever. Came under observation on the third day of the attack. The giving of calomel, barley water and bismuth mixture for two days, followed by a gradual resumption of nursing, effected a cure on the fifth day. The Shiga type of organism was present.

13. K. M., eight months old, good general condition. Diarrhea without vomiting or fever. Stools fluid, mucous, no blood, eight to ten in twenty-four hours. Child sick three days before coming under observation; then calomel, bismuth mixture and barley water brought about a rapid recovery.

14. G. S., seven months old, excellent condition. Diarrhea with eight or nine fluid, very mucous stools without blood. On the eighth day of illness the child was brought to the clinic. Calomel and bismuth with barley water were followed by the reduction of stools to three in twenty-four hours and by the change in character to normal.

Of the breast-fed cases whose records are complete none died, all ran a very mild course, the average being three to four days after coming under observation. Save for the bacteriological findings there was nothing to indicate that their sickness had any relation to true dysentery. These cases, moreover, with hardly an exception, were in well-nourished children. Blood was observed in but one case.

Type of Infection.—There were 42 cases in which the acid type of organism was found; 15 were infected with the alkaline or true Shiga type; in 5 cases both types of the organism were found. Of the 42 acid infections, 9 were classified as mild cases, 21 as moderately severe; 10 as severe; 2 not being classified. Of the 15 true Shiga infections, 5 were mild, 6 moderately severe and 4 severe. Of the 5 mixed infections 1 was mild and 4 moderately severe.

From this it will be seen that in the acid type of infection, as well as in the true Shiga type, the moderately severe cases were most numerous, and there seemed to be no difference in the severity of the disease attributable to the type of infection.

We did not use at all, for diagnosis, the agglutination reaction of the blood of the patients. It has been proven in children as well as in adults that this reaction, while often present, is uncertain and unsatisfactory for the reason that it appears late, not before the end of the first week, and often not before the second or third week, and may disappear early in the prolonged cases; so that we can make our diagnosis by an examination of the stools much more easily and more satisfactorily than by the blood.

Treatment.—As outlined above, the majority of the cases were treated by the usual methods both as to their management and diet. Milk, whether breast milk or cow's milk, was immediately discontinued; barley water, broth or some proprietary food, or, rarely, albumen water being given in its place; it was only resumed when the acute symptoms had subsided. Catharsis by calomel

and castor oil was the invariable rule. When there was great irritability of the intestines with tenesmus and numerous small stools, rectal irrigations, without or with paregoric by mouth, were employed. For temperature that gave rise to nervous symptoms irrigations and alcohol sponging were resorted to. A bismuth mixture was used in a few cases.

Serum Therapy.—There were in all 10 cases in which the serum was injected; 4 were infections with the acid type of organism and were given Harris serum; 6 were infections with true Shiga organism and were given Shiga serum. Only the severe cases were subjected to this treatment, as it was found that in dispensary practice the mothers would not return with the patients after injection unless the disease was apparently serious.

Of the injected series, Cases 1 and 2 were given 10 c.c. of Harris serum and did not return after the injections. Case 3, after receiving 20 c.c. of Harris serum, showed decided improvement; after the injection of 10 c.c. additional this was still more marked, but the child died of marasmus three weeks later without any return of the diarrhea. Case 4 was already improving on irrigations before the injection of the serum, so that no conclusions can be drawn. Case 5 showed decided reduction in the number of stools and improvement in their character after the injection of 10 c.c. of Shiga serum on two successive days. Case 6 received 20 c.c. Shiga serum, but the improvement in the child's condition could not be attributed to the injection.

Case 7 received 10 c.c. of Harris serum when moribund.

Case 8 (the severe case quoted above) improved very markedly after two injections of 20 c.c. each of Shiga serum, but only after an interval of three days, during which time there were additional stimulation and change of diet, so that the effect of the serum is doubtful.

Cases 9 and 10 were apparently uninfluenced by the injection of Shiga serum.

A rash similar to that seen after the employment of diphtheria antitoxin was observed in only one patient, notwithstanding the fact that the quantity of serum injected was very much greater than that ordinarily used in diphtheria.

The difficulties of administering the serum in outdoor practice must be emphasized. The quantity of serum of the present strength necessarily employed is large and must often be injected into an emaciated child, producing a swelling of a size alarming to the laity. Objection arises also on account of the pain of the injection.

From an analysis of these 62 cases observed by us, it seems that certain points are worthy of special note.

1. The unexpectedly great prevalence of the dysentery organism in cases of diarrhea in infants, at least during the summer months. Thus out of 64 consecutive cases examined in the Vanderbilt Clinic, 62 were positive.

As has been mentioned before, this is the first large series of cases examined seriatim that has been made and the result is certainly striking. It is all the more so when we consider that these were cases in dispensary practice, where with the severe the very mildest cases may be seen. Duval and Bassett examined 25 successive cases and found the organism in 19, but it should be stated that the patients were observed in a sanatorium at a distance from Baltimore where, of course, only the more severe cases were sent from the dispensaries, while ours were all ambulant patients and their stools were examined whenever there was the slightest sign of any digestive disturbance. Our cases were also seen very early whereas, in hospitals, the cases are rarely seen until their initial symptoms have passed.

2. All types of diarrheal disease, as characterized by their clinical symptoms, are to be found among these cases. Some were examples of severe and some of mild ileocolitis; others could only be classed as the mildest form of intestinal indigestion. The course of the disease, while usually short, was prolonged in 8 cases.

3. As compared with cases of "summer diarrhea" of other years those in this series were in general much milder; and possibly this was due to two factors: (*a*) The cool summer. (*b*) The increasing knowledge among the tenement population of the care of infants and their food.

4. The striking number of breast-fed infants, 14 in 62 cases, more than 20 per cent. of all.

In the series of Duval and Bassett previously mentioned, there were 4 breast-fed cases and a few others in addition have been reported. The great number in our series is accounted for by the fact that all stools from patients with diarrhea were examined. As will be remembered of our 14 breast-fed children, not one was severely or even moderately ill, and only one had blood in the stools. Such cases would therefore not be sent to hospitals, and so usually their stools would not be available for examination.

5. The serum treatment was not given in a sufficient number of cases to warrant any conclusions. While of apparent benefit in some cases, there were others in which no effect whatever was noticed. It may be that larger dosage is necessary; but, if so, the serum must be more concentrated than at present.

A FACTOR IN THE ETIOLOGY OF DISTORTED NASAL SEPTA.

BY CHAS. E. QUIMBY, M.D.,
OF NEW YORK.

One needs but a moderate acquaintance with the literature of this subject to be impressed by the uniformity with which the several authors insist that all such conditions are due to their own pet cause; or, if they admit any other possibility, that other causation is the rarest exception. Wherefore, I desire to state clearly at the outset

that I regard the factor to which I wish to call—or, more properly—to recall attention, as simply one among many causes of the condition under consideration. I am inclined to think, however, that it receives less attention than it deserves.

My position is stated very simply and briefly thus: That deflected and distorted septa are in many cases developmental defects and require no other cause for their explanation than pure chance. It is understood that cases involving definite new growth of either cartilage or bone are not included.

Recognition of the fact that deflected and distorted septa are frequently associated with high palatine, and narrow alveolar arches is not new: indeed, it is so old as, apparently, to have lost its early attire of explanatory causation and to require fresh dressing out by each new arrival in the field of rhinology. But the significance of the equally ancient observation, that in these cases there is quite constantly a difference in size and form of symmetrical parts of the facial skeleton, seems to have been quite forgotten.

One other fact is to be added: It is that narrow alveolar arch and asymmetrical facial development are found most frequently in association with triangular-shaped teeth and varying grades of irregular dentition, but seldom with the straight-edged teeth and regular dentition.

Given the above facts, our propositions are as follows: The development of the facial skeleton is never perfect; failure in development is frequently so extreme as to prevent union of the two halves, shown in harelip and cleft palate; asymmetry in development is so frequent as easily to be recognized in most faces by the eye alone. These are statements which no one will presume to question. But with their acceptance it hardly seems possible for one to object to the proposition, that in some cases the superior maxillary bones unite at an unduly acute angle; that the vomer and triangular cartilage, one or both, fail of proper articulation with the maxillary, palate and ethmoid bones. From this point the production of deflected and distorted septa is merely a question of mechanics.

Normally the developmental forces which spread the alveolar arch give a vertical resultant which is balanced by the septal tissues. But with an abnormally acute angle between the lines of pressure in the maxillary bones this vertical resultant is increased; and, if the opposing septal resistance is at the same time weakened by imperfect articulation either above or below, distortion and further deflection of those tissues are a mechanical necessity. If there is still further, at the time of the second dentition, when the face is being most rapidly developed, an eruption of triangular teeth with the almost inevitable failure of proper lateral coaptation, all the expansive force which normally comes from the growth of the teeth is lost and the distortion of the septum increases at this time instead of diminishing. The possibility of the above sequence of events certainly cannot be denied; that it does happen is a matter for clinical proof. The effects of inflammatory changes in the septum, resulting from the injury it suffers, might very properly be considered, but the mechanical side of the case seems sufficient for the present.

My own attention was called to these relations by the following clinical experience, which seems to substantiate the claim that the assumed errors of development do occur: A young girl under my care developed, during her eleventh year, a moderate tendency to mouth-breathing. Knowing that in all her earlier life her respiration during sleep had been as perfect as possible, I attributed it to a cold and neglected it. A year later, however, it had increased so that it led to an examination of the nose. There was then found a decided deflection of the cartilaginous septum with general hyperemia and swelling of the membranes. The left plate of the vomer was bent pretty sharply outward at its posterior end and apparently was not in articulation with the palate bones in the central line. Nothing abnormal could be seen in the vault of the pharynx. Not being prepared for an operation she was treated through the winter simply with sprays, but without any appreciable relief. At that time her second dentition was well advanced. She had inherited from her father the triangular teeth and they had come in very irregularly. The two lateral incisors had their inner edges rotated backward, and the whole tooth carried inward until it was overlapped by the central incisor fully one half its width. Not being satisfied with the physiology upon which advice seemed based, when a dentist was consulted regarding the regulation of the teeth, and on account of the timidity of the child, I determined to do the regulating myself. Time forbids details of the work; suffice to say that after some study of the matter it became evident that to act on the errant teeth separately, while it might bring them into line, must cause them to stand out like a fringe unless the alveolar arch was broadened, and that, therefore, this was the first thing to be done. It was equally clear that this could be done only by separating the maxillary bones. To this end a band was placed about the second bicuspid and first molar of each side that, if possible, the effect of pressure might be on the maxillary bones rather than the teeth. Pressure was made by means of a small jack-screw upon the two bands. It was made very light at first and increased slowly, but in about two weeks the central incisors had been separated a little over one-eighth of an inch, while the teeth under pressure had not been obviously moved in the bone. Soon after this, and before any effort had been made to move the lateral incisors, the child came to me asking what had happened that she breathed so much more freely.

An examination showed marked decrease in the flexion of the cartilage but no appreciable change in the vomer. When her attention was called to

it she was able to recognize clearly with her tongue the opening between the two bones in the roof of the mouth. It was evident that the bones had been separated mostly at their anterior point, as the groove in the mouth did not extend through the hard palate.

She very soon lost all tendency to mouth-breathing, and this condition of perfect respiration during sleep has continued now for three years, while the hyperemic condition of the anterior nares has long since disappeared. The difficulty experienced in this case in bringing the teeth into such coaptation that they would not again become twisted upon release of the maxillary bones has convinced me that only by a special dispensation of Providence can triangular teeth erupt in symmetrical outline. I am able to explain the results only upon the assumption that the bending of the septum was due to imperfect articulation and undue vertical pressure from the developing maxillary bones; that this pressure was relieved by separation of the maxillæ and that the cartilage was pressed into the groove thus formed. If my conclusions are correct children with irregular teeth, high palatine, or narrow alveolar arch and distorted nasal septum should be treated by the dentist and rhinologist together. Of course this work cannot be done after ossification at the line of maxillary union is well advanced; or after puberty. Yet, before this time the teeth are seldom sufficiently developed to make a satisfactory final regulation if they are of the triangular variety. Hence the earlier work should be directed specially to the correction of the nasal defect and the final regulation of the teeth left for some years later.

I am well aware that a single case does not establish a rule or principle; but the object of this paper is to establish the exception.* That deflected septa may, in some instances, find sufficient explanatory causation in simple developmental defects seems clearly shown in the above case by this sequence of events: development of mouth-breathing coincident with an exceedingly irregular second dentition following perfect respiration in early life; the discovery of a deflected septum nearly closing the right nostril; almost complete disappearance of the septal flexion, a subjective appreciation of freer respiration, and entire cessation of mouth-breathing following directly upon separation of the maxillary bones. With nasal work limited almost entirely to cases associated with pulmonary disease I have had little further opportunity of investigating the subject in children, but rather careful observation of adult cases for the past three years has caused no little surprise at the frequency with which deflected and especially dislocated septa are associated with the other two developmental defects, and has tended to confirm the original conviction as to the frequency of their etiological relations.

* Since writing the above several cases have been brought to my attention showing distorted septa with each form of defective arch in which results promise to be equally satisfactory.

ON THE ABORTIVE TREATMENT OF GONORRHEA IN THE MALE.*

BY FREDERIC BIERHOFF, M.D.,

OF NEW YORK.

The attempts to devise an abortive treatment of gonorrhea did not originate in the immediate past, but were already tried in the days preceding the discovery of the gonococcus, by Ricord, Diday and others.

To those familiar with the severity of the complications and sequelæ of gonorrhea, as well as its wide spread, through all the strata of society, the possibility of aborting this disease, in its earliest hours, or days, must appear almost as a blessing, if the cure can be effected without harm to the patient. There are two methods of achieving this result now at our disposal, viz., the *prophylactic,* by means of which those gonococci which may have obtained lodgment in the urethra are killed immediately, or shortly after the infective coitus, and the development of an inflammation prevented; secondly, the *abortive,* by means of which the already-developed gonorrheal urethritis is cured in a few days, and the pathological changes, which such an inflammation produces, are reduced to the minimum.

The prophylaxis, which is being more and more adopted, is the ideal treatment. It is possible in either of two ways; either through the use of a reliable condom (preferably of fish-skin), or through instillations, injections, etc., of the gonococcicide drugs, immediately after coitus. Thus Haussmann, Kopp and Blokusewski recommend the instillation of a few drops of a two-per-cent. solution of nitrate of silver. Probably the greatest credit, in this direction, is due to E.R.W. Frank, and Welander, for their studies in the prevention of gonorrhea, by means of protargol solution. Both, working independently of each other, succeeded through their inoculation experiments with fresh gonorrheal pus, in demonstrating conclusively that it is possible to *prevent* gonorrhea. I have adopted the prophylactic measures, in my practice, and recommend my patients to instil 2 to 3 drops of a 10 to 20 per cent. solution of protargol in glycerin into the fossa navicularis, as soon as possible after the suspicious coitus. In one case it was possible for me to discover the gonorrheal infection within ten hours after the suspicious intercourse, and to abort the disease with a single injection of 8 c.c. of a two-per-cent. protargol-glycerin-water solution. This case, which I have not included among the thirty cases referred to further on, in this article, I was able to control exactly, and I found, on the first examination, *distinct,* although few, gonococci, in the urethral scraping; at several points there were already distinctly gonococcus-bearing pus-cells. Control examinations were made after one, four, eight, twenty-four and forty-eight hours. Already after *one hour* the secretion, which was called forth profusely by the injection, was free

* Read before the German Medical Society (New York), December 7, 1903; Harlem Medical Association (translation), January 6, 1904.

of all germs, and remained so, which fact I was able to determine by repeated subsequent control-examinations, during a period of several months. The discharge rapidly lost its purulent character, after the cessation of treatment, to become purely epithelial within twenty-four hours, and disappeared entirely after another twenty-four hours.

As is the case with the prophylactic, so the possibility of an abortive treatment depends upon the fact that the gonococci, in the earliest days, when not abnormally virulent, or brought to virulence through irritants, or injury, or a markedly diminished power of resistance of the tissues, have a tendency to remain confined to the fossa navicularis, because the walls of the fossa navicularis are covered with stratified, squamous epithelium, which, as is well known, is resistant to the action of this germ. I am of the opinion that many a gonorrheal infection of low virulence dies out, upon the epithelium of the fossa navicularis, without its bearer having been aware of the fact of the infection. As a result, in all probability also of this power of resistance, the changes in this part of the urethra, demonstrable after the cure of a gonorrhea, are very slight.

If we see a case of gonorrhea early, that is, at the very beginning of the appearance of the visible discharge, then we notice, in addition to the usual reddening of the urethral orifice, beginning hypersensitiveness and a rapid increase in the number of leucocytes, as proofs of the fact that the infection has passed beyond the fossa navicularis, and has begun to develop on and penetrate between the cylindrical epithelia of the pars cavernosa. We also notice that the gonococci which, in the first hours after infection, and so long as the process had been confined to the fossa navicularis, had almost entirely been *extracellular,* now more and more come to lie *intracellular* (I refer to secretion obtained with the loop, just within the meatus, without the exertion of any pressure or stripping of the urethra, the secretion then being gently spread out, on the slide, with the loop. Not by drawing it off with another slide). The more the process extends over the pars cavernosa, and the deeper into the tissues that the infection penetrates, the less are, in my estimation, the chances for the success of any abortive treatment. The sooner one begins with the treatment, the greater are the chances of success, in the absence of complicating conditions. The complicating conditions are the presence of remains of preexisting disease; for instance, chronic gonorrheal infection of the lacunæ, glands of Littré, or prostate; and congenital malformations of the urethra, such as paraurethral passages, or abnormal width, or depth of the lacunæ.

The method of treatment has differed, with different investigators. Ricord, Debenay, Diday and others employed injections of nitrate of silver, in solutions up to five per cent. in strength. Delefosse instils a two to two and one-half per cent. solution of the drug, by means of the Guyon instillation syringe, into the urethra, applying it to the membrane, from the bulb to the meatus. This is repeated on the following day. If, on the third day, gonococci are still present, a two-thirds to one-half per cent. solution is employed. Pontopiddan reports on 160 cases treated with the two per cent. solution. He applied several drops to the fossa navicularis, after the patient had urinated. In one-third of his cases the disease was aborted; in the rest, the disease ran a mild course. Ullmann injected 3.0 to 5.0 of a two per cent. solution, 4—5 cm. into the urethra, the solution being retained for two minutes; he also reports positive results. Welander recommends, in fresh, at most two to three days' old cases, that the urethra be first wiped clean, and, following this, the injection of a two per cent. solution, which is retained for two minutes. Fèleki recommends, in fresh cases, the penciling of the urethral wall with five per cent. solution, through the endoscope. He states that, where the secretion was slight and of a serous character, one application sufficed; in other cases it had to be repeated, after two to three days. He claims to have had no complications.

Engelbrecht recommends irrigations, according to the Janet method, with 500.0 to 600.0 of a one-fifth to one-third per cent. nitrate of silver solution, after preceding cocainization of the urethra. He claims to have cured nine-tenths of his cases in two days, after four applications. Neisser recommends early irrigations with nitrate solution of 1 : 3,000 to 1 : 1,000 strength; Finger and Jadassohn report that they have had no success with this method. Tarnowsky is reported to have cured 40 to 50 per cent. of his cases of acute gonorrhea, in four days, by means of nitrate of silver solution; but reports that, in those cases which resulted negatively, the symptoms of inflammation were increased to such a degree that the treatment had to be abandoned. According to the reports of most of the observers, the reaction following the abortive attempts with nitrate of silver solution is very severe and, at times, severe complications arise, resulting even in death, as in a case reported by Cullerier and Guyon.

Another variety of the abortive treatment is the application of Janet's method and its modifications. The irrigations with permanganate of potash are recommended by Janet himself, by Valentine, Goldberg and others; Wossidlo, Horwitz, Weiss and Christian express themselves against the method, as an abortive.

Since we have come into possession of the various drugs, such as protargol, albargin, ichthargan, argyrol, etc., which destroy the gonococcus where they can reach it, while they irritate the mucous membrane but little, various investigators have tried the abortive treatment with these remedies. Thus Ahlstrom reports on 100 cases which he treated abortively. Twice daily, for the first four or five days, he injected 5.0 to 10.0 of a two to four per cent. solution of protargol. For the next three to five days the patients themselves injected with a one to two per cent. solution, which they retained in the urethra for ten to fifteen minutes.

In only 13 per cent. was there a negative result; in 8 per cent he saw complications. He must have had model patients to deal with, since the large majority of patients complain, even with injections of a one per cent. solution, of almost unbearable pain, when the solutions are to be retained in the urethra for ten minutes. Or are our American patients, perhaps, weaklings, when compared to the European? I have found, too, that with such strong solutions, the other symptoms of irritation are so severe that I should hardly recommend them. Neisser and Blaschko speak in favor of the early treatment of gonorrhea, with three to four per cent. protargol solution; Wossidlo, on the contrary, saw no benefit from it, but, rather, unpleasant results.

Casper states that he cannot say of a single case that the beginning gonorrhea was checked by means of the abortive treatment, and would, therefore, recommend its abandonment under all circumstances. Von Zeissl states that he cannot recommend it. Finger states that he believes the rapid cure of gonorrhea to be an impossibility.

Thus we see that the views for and against the abortive treatment of gonorrhea are varied.

Before the urological division of the Thirteenth International Medical Congress, Frank reported upon a series of 60 cases which he had treated according to the abortive method devised by Lewin and himself. The method, whose application and trial I had the pleasure of witnessing, during their experiments, is reported as follows: "After the microscopical diagnosis has been made, the patient passes water. If the second portion of the urine is clear, the anterior urethra is next irrigated under light pressure, with one-quarter per cent. protargol solution, until the fluid returns clear. If the patient is very sensitive, a solution of cocaine, to which, as a precaution, some protargol has been added, is injected into the urethra. Following this we make a large irrigation of both portions of the urethra, with a similar protargol solution, according to Janet's method. The solution is allowed to flow until the patient notices a desire to urinate; that is, about one-quarter to one-half liter, whereupon he empties the bladder. This procedure is repeated upon the following two days." Frank reports upon 60 cases treated by this method. In 27 (45 per cent.) the result was positive; that is, after three irirrigations (in one instance after a single one) the gonococci were definitely destroyed. In 26 cases the result was negative. In three of these negative cases gonorrheal infection of para-urethral passages was discovered; after incision of the passages, further two to three irrigations cured the cases. In two other cases, the presence of congenital folds and valves, with narrow meatus, was the cause of the negative result. In 21 cases the prostate was infected, and Frank believed that this infection had already existed at the time the attempts to abort the disease were begun. The remaining seven cases withdrew from treatment, to present themselves later as cured.

My observations, made at the time of Frank's experiments, determined me to test this method of abortive treatment. Although I have, as a result of circumstances, slightly modified the plan of treatment, to meet the requirements of my patients, it remains, in principle, that laid down by Frank and Lewin. In order to be able to control the cases more exactly, I employed it only in the cases of intelligent private patients, who, as soon as they realized the aim of the measures, were willing to help me with all their power. The method employed was as follows: A microscopical examination of the secretion was first made. If the discharge was slight, and if the majority of the gonococci still were extracellular, then the protargol solution was employed in the strength of one-sixth to one-third per cent. If the discharge was at all pronounced, or if the greater part of the gonococci were intracellular, then a one-third to one-half per cent. solution was used. The method was employed, naturally, only in those cases in which the second urine was clear. After urination, the urethra was anesthetized by an injection of a mixture of 4 c.c. of a one per cent. cocaine solution and 4 c.c. of a one per cent. protargol solution. After this the anterior urethra was cleansed with 150 c.c. of the protargol solution. Following this, an irrigation of the whole urethra was made, according to Janet's method, with 150 c.c. of the solution. The patient then emptied his bladder of the irrigated fluid. This irrigation of the entire urethra, with immediate emptying of the fluid, was repeated from one to three times in the same sitting, so that the urethra was flushed four to eight times. In addition, the patient was given a solution of protargol, one-half per cent., with which he was instructed to inject three to five times during the day, and to retain the fluid ten minutes each time. During the succeeding days, if the gonococci had disappeared, the strength of the solution and the quantity of fluid injected were diminished, to be suspended, if the result was positive, on the fourth or fifth day, at the latest. The injections by the patient were also diminished and suspended in a similar manner. Then followed the usual provocative tests and control examinations. I will state, at this point, that I consider the continued absence of discharge, and the absence of gonococci from the shreds (which should be only minimal and chiefly epithelial), from the prostatic secretion (which must also be free of pus-cells), and from the urinary sediment, and this in spite of the tests of cessation of treatment, indulgence in alcoholics, irritating injections, and coitus condomatus, to be a proof of cure, if, after control examinations covering a later period of several weeks, the patient still remain free of discharge and gonococci. Cultures, I believe, should be employed in every doubtful case. I do not, however, believe them to be an absolute necessity to determine the fact of a cure.

In all, I have employed the method in 30 cases (up to Nov. 1, 1903). In 15 cases (50 per cent.) the result was positive; in 15 (also 50 per cent.)

negative. In the positive cases, the gonococci had definitely disappeared in 12 on the second day, in one on the third day, in two on the fourth day. The duration of the treatment and tests varied from five to twenty days. In two cases the fresh gonorrheal infection occurred in the persons of patients who were under treatment for old, endoglandular, non-gonorrheal prostatitis, and in neither of the cases did the gonorrheal infection extend to the prostate. The period of incubation was two days in 5 cases, three days in 4 cases, four days in 3, five days in 1, six days in 1, two to three weeks in 1 case. The patients presented themselves on the first day of the discharge in 10 cases, on the second in 1 case, on the seventh and eight days in 2 cases, on the thirteenth day in 1 case, and on the forty-seventh day in 1 case. In none of these cases was it a first infection; in 4 cases it was a second, in 4 a third, in 4 a fourth. In the remaining 3 the exact number of preceding infections was not obtainable, but in all it was at least the second infection.

Of the negative cases, the gonococci had definitely disappeared in two cases after the fifth day (so that I might even be excused were I to class these cases as positive results); in 3 cases after the tenth day, in 1 after the sixteenth day, in 2 after the twenty-first day, in 1 after twenty-two days, in 1 after thirty-five days, in 1 after thirty-six days, in 1 after forty days; one case is still under treatment (Nov. 1, 1903). Two cases withdrew from observation before the gonococci had disappeared. The duration of the treatment and testing varied from fourteen days to a period of over five months (in the case of the patient still under treatment, where an infection of a lacuna of about 3 cm. in depth has protracted the disease abnormally). The period of incubation was two days in 4 cases, three in 5 cases, four in 1 case, five in 1 case, six in 2 cases, three or six in 1 case, and twenty days in 1 case. Ten patients presented themselves on the first day of the discharge, 1 on the second day, 3 on the third, 1 on the sixth. In 3 cases it was a first infection, in 5 a second, in 4 a third and in 3 the number was impossible to determine, although it was at least the second. The cause of the negative result was, in 6 cases, the involvement of the glands and lacunæ of the anterior urethra; in 1 case the infection, in a mild degree, of the prostate, in a patient who, in spite of my admonitions, repeatedly subjected himself to sexual excitation. In 1 case (one of the patients who withdrew from treatment), the urethral glands and prostate became infected, upon an old, postgonorrheal catarrhal inflammation, for which I had had him under treatment prior to his gonorrheal reinfection. In six cases there was no demonstrable cause for the negative result; but these were all cases which could be discharged as cured in from three to five weeks; in 1 case (the second patient, who withdrew from treatment because he had to return to his out-of-town home), the gonococci were almost entirely gone at the time of his departure.

In only one of the cases (one in whom the abortive attempt was begun with argyrol, to be later supplanted by protargol), did I notice any graver complication, and this was a gonorrheal tendovaginitis of the extensors of the fingers of the left hand, at the forearm and wrist, which appeared on the third day of the discharge and the fifth following the infection. The course of the complication was short and mild, and the result a complete restitution of function.

Several of the patients complained of an unpleasant sensation of burning and tenesmus after treatment, which sometimes lasted one-quarter to one-half hour, even when the weaker solutions were used. This was, however, but little greater than where the usual irrigations form the treatment. Isolated cases showed an extraordinary sensitiveness toward the drug, in that periurethral edema, of varying severity, developed. This disappeared rapidly, however, and formed no real obstacle to the treatment. Almost all of the cases, negative as well as positive, were subjected to control examinations, after an appreciable time had followed their discharge as cured, and all were found to have remained well, and to be still free of gonococci.

That a posterior urethritis (prostatitis) developed in only two of this series of thirty cases (6.6 per cent). I regard as the best argument for the utility of the abortive treatment. If we compare these 6.6 per cent. with the high percentages reported by investigators, under other forms of treatment, then we might say that, if the abortive method did nothing else, it would still be available. According to Leprevost (1884) a posterior urethritis occurred in one-sixth of his cases; Eraud (1886) saw it in 80 per cent., Jadassohn (1889) in 87.7 per cent., Letzel (1890) in 92.5 per cent., Rona (1891) in 62 per cent., Phillipson (1891) in 86.6 per cent., Dind (1892) in 93 per cent., Ingria (1893) in 59 per cent., Finger (1896) gave it as 63 per cent. in his private patients, and 82 per cent. among his dispensary clientèle. In 1890 he gave the figures as 33.5 per cent. Frank (1900) saw it in 32.25 per cent. among his dispensary patients. In his statistics on the abortive treatment, he stated that infection of the prostate occurred in 35 per cent., but as previously remarked, he was of the opinion that this had occurred before the beginning of the treatment. In my two cases it occurred, as before mentioned, in one case following (and, I believe, as a direct result of) repeated sexual excitation during the acute stage of the disease; in the second as a result of a preexisting catarrhal inflammation of the prostate.

That the lacunæ and urethral glands became involved in 6 cases (20 per cent.), I do not consider as an argument against the abortive treatment. The solution may have been too weak, since in only one of the negatively resulting cases was a one-half per cent. solution employed, and this in the case with an old inflammation of the urethral glands and prostate.

I know that the number of my cases is too small to allow me to draw definite conclusions; neither do I wish to claim that the method mentioned in this article is the best one. I only wish to present the experiences I have gained through its application as proofs of the facts: That the abortive treatment of gonorrhea is possible; that if it be employed *early*, the percentage of cases in which a positive result may be obtained is a fairly large one; that when one employs only those drugs which, while they kill the gonococci, do not injure the mucous membrane, the percentage of complications will, most likely, be smaller than has heretofore been supposed; and, finally, that, should the attempt to abort the disease fail, the patient will not have been injured.

DIFFERENTIAL DIAGNOSIS AND TREATMENT OF CHANCROID AND CHANCRE.

BY C. G. CLARK, M.D.,
OF NEW YORK;
ASST. SURGEON, NEW YORK HOSPITAL HOUSE OF RELIEF, GENITO-URINARY CLINIC; FORMERLY ASSISTANT SURGEON, NEW YORK HOSPITAL, O. P. D., GENITO-URINARY DEPT., NEW YORK.

The differentiation between soft and hard chancres, or chancroids and chancres, is a point upon which a great deal depends, and yet it is one of the hardest problems at times with which the genito-urinary surgeon contends. It is the purpose of this paper to take up the differential diagnosis of these two exceedingly common venereal sores and to outline the treatment (local) of each. If the sore be soft the local treatment will be all that is necessary in the majority of cases; if hard, constitutional symptoms are sure to follow sooner or later, and the sooner these come the better it is for the patient. It is, in the majority of cases, absolutely impossible to convince the patient that two years' treatment is necessary to cure a disease, the only manifestation of which he has seen has been a small insignificant sore on the penis. For this reason, even if the diagnosis is reasonably sure, it is better to wait until constitutional symptoms have manifested themselves before beginning the systemic treatment.

In diagnosing, the first thing to bear in mind is the general appearance of each sore. Then if the sore be typical the diagnosis is easy. A hard or syphilitic sore is generally small and insignificant, situated on or near the corona and generally near the frenum. The edges are indurated and its base is excavated and has a smooth floor with little or no secretion. On the other hand, a soft sore may appear anywhere on the penis, is generally multiple and larger, its base being irregular and covered with a purulent discharge.

Other important points to aid in the diagnosis are as follows: *Incubation period.* In a chancre it is always more than a week and generally from ten to fourteen days. In a chancroid it is always less than a week and generally from two to three days. When this can be positively determined it is a great aid in our diagnosis, but in a great majority of patients, and especially hospital patients, it is next to impossible to determine at just what time the infection took place.

Adenitis.—The inguinal glands are enlarged in both cases, but are much more apt to break down in chancroidal infection. In the syphilitic sore they are more shotty, uniformly enlarged on both sides, and do not break down as a rule. As the disease progresses the cervical and epitrochlear glands become enlarged. This never happens in chancroidal infection.

Multiplicity of Sore.—As stated before, the hard sore is generally single and the soft may start singly, but almost invariably the discharge causes more sores to appear.

Position of Sore.—In more than 1,000 cases of syphilis I have found that in two-thirds the sore was found on the corona and near the frenum. The chancroid may appear at any point where the membrane was abraded and the infection entered.

The above points will aid in diagnosing the majority of cases, but in a few it is absolutely impossible to state positively the exact nature of the lesion. This is especially true of the cases where both infections occur simultaneously. These patients will develop a soft sore in a few days after intercourse, which will not yield readily to treatment and by the tenth and twelfth day will become hard. In other cases the sore may be indurated from excessive burning with strong caustic and mislead the physician. As the treatment is about the same in both cases, however, the diagnosis only helps us in making a better prognosis, and if it is at all in doubt we should be very guarded in the prognosis until sufficient time elapses to allow secondary symptoms to appear.

I have found the best method of treating these cases to be one of absolute cleanliness. Nothing is to be more condemned than the excessive cauterization practised by so many physicians in all cases of venereal sores.

In either case, whether chancre or chancroid, the first thing to do is to thoroughly disinfect the lesion and to wash the entire penis with green soap and water, then get rid of the soap with alcohol or ether and thoroughly cleanse the sore or sores with a solution of bichloride of mercury, 1 in 2,000. The entire penis is then wrapped in gauze saturated with the above solution, and the patient instructed to keep this wet for about twelve hours. The gauze is then removed and the sores are dried and thoroughly dusted with aristol (pure). This is an excellent dusting powder and keeps the sores dry and has the advantage over iodoform of being odorless, and that is one thing that these patients who are generally hypersensitive most appreciate. After this thorough dressing the patient generally requires nothing but a solution of bichloride (1 in 5,000)

and the aristol. The sores should be washed every three or four hours, dried, and a fresh application of aristol made.

This treatment is generally all that is necessary for an average case of chancroids. If, however, there are complications, other procedures may be necessary before the sores can be thoroughly cleansed. One of the most common complications is phimosis or paraphimosis. This should be relieved by slitting up the dorsum and laying the glans bare. The rest of the operation for circumcision may be done later. Care should be taken that the cut surfaces of the prepuce do not become infected. They should be covered with aristol.

The above treatment applies to chancroids and all mixed sores. If the diagnosis of chancre be positively made the same procedures may be followed, but I have found that if, after cleansing the sore, a dusting powder of aristol and calomel (equal parts) is used the results are better. Under no circumstance should the patient be put upon antisyphilitic treatment until the diagnosis be confirmed by the appearance of secondary symptoms.

I believe that if this tretment be followed out in all cases (especially chancroids) that the sores will heal much more readily and the danger of complications will be arrested. The old custom of burning every venereal sore with pure carbolic acid or nitric acid only aids in delaying the healing process and makes an unsightly scar in a great many instances.

THE OCULAR SIGNS OF SYPHILIS.*

BY WENDELL REBER, M.D.,
OF PHILADELPHIA.

It would be of much interest and decided value if it could be shown by statistics just what proportion of syphilitics present ocular lesions, but it is doubtful whether this will ever be accomplished. Patients thus afflicted are not prone to tell all they know even under the most artful questioning, so that all figures bearing upon this question must naturally represent a lower percentage than actually obtains. Moreover, syphilis may be contracted venereally and yet without the knowledge of the patient (as for instance, urethral chancre) and if the secondary symptoms are not marked such a patient could conscientiously aver that as far as his knowledge went he had never been infected. Finally, many cases of syphilis are contracted innocently, and thus without the slightest supicion on the part of the patient of the nature of their malady. Should anyone be disposed to smile at the idea of innocent syphilis, let them consult Bulkley (Syphilis Insontium, p. 894), who has brought together authentic histories of over 9,000 cases of chancre situated elsewhere than on the genitals—and be convinced. There is no tissue of the eye or its appendages that has not been invaded by syphilis. Just what percentage of syphilitics exhibit such ocular invasion is, as has been said, impossible to say. DeWecker, the noted French ophthalmologist, says 15 per cent. Alexander (Syphilis und Auge, 1889) quotes six foreign ophthalmic observers besides himself. Their combined statistics include 138,000 cases, among whom 2,998, or 2⅛ per cent., furnished a syphilitic history. In 1,385 ophthalmic cases with a specific history, Alexander (*loc. cit.*) found the ocular muscles affected in 15 per cent., the uveal tract in 24 per cent. and the optic nerve and retina in 48 per cent. of all the cases.

Syphilis in the visual sphere may assume any one of the four usual phases, namely the primary sore, the secondary, the tertiary and the hereditary phase.

The most usual site for the primary sore is at the margin, or just within the margin of the lids. In his work (*loc. cit.*), Bulkley reports 159 such cases. They may be induced by poison carried to the eye by the finger, or, as frequently occurs, by the use of the tongue for the removal of foreign bodies in the eye. This custom is not uncommon among the lower classes, and if oral syphilis be present in the one who performs this absurd office an initial sclerosis appearing on the lid is entirely possible.

Secondary syphilis may affect the cornea, the uveal tract or the optic nerve and retina, but it certainly has a marked predilection for the uveal tract. It is a fact as well known to-day to syphilologists as to ophthalmologists that the iris is quite as likely to be the seat of secondary signs as the skin, the oral and the rectal mucosa. The percentage of cases of iritis in which syphilis is operative is stated by Von Arlt to be 29 per cent.; by de Wecker, 55 per cent.; by Mauthner, 70 per cent.; Schnaübel, 48 per cent.; von Graefe, 60 per cent.; Knapp, 30 per cent.; and Alexander, 60 per cent., all quoted by Alexander (*loc. cit.*). This makes a mean percentage of 50 per cent., which agrees perfectly with the figures of Brunson of the Hot Springs of Arkansas, who has probably seen more syphilis than any ophthalmologist in this country. So that every iritis is open to the suspicion of being syphilitic until trauma, tuberculosis, microbic infection or the rheumatic diathesis have been plainly shown to be causative. Choroiditis is perhaps as frequently syphilitic in origin as iritis, and is even more valuable diagnostically than iritis, inasmuch as it almost invariably leaves scars in the choroid that may be studied years afterward in cases of doubtful tertiary aspect. Iritis on the other hand may be so successfully treated as to leave no telltale traces behind. But should there remain attachments between the iris and the lens capsule, they are often of great assistance in establishing the probable history of a previously active syphilis.

The optic nerve is a bit of tissue that is as often tertiary as secondary in its involvement. Nine

* Read before the North Branch of the Philadelphia County Medical Society.

German observers found optic neuritis of specific origin in 56½ per cent. of 981 cases. Oftentimes this was a part of a central tertiary syphilis, but the fact stands out that this bit of highly specialized tissue is peculiarly susceptible to the action of the syphilitic poison.

Most frequent of involvement in the tertiary process, however, are the intra- and extra-ocular muscles. Alexander (*loc. cit.*) found 56 per cent. of 269 extra-ocular palsies to be luetic, while 77½ per cent. of 76 intraocular palsies were definitely syphilitic. This is a very high percentage, but Alexander is a very high authority and his figures are pretty well supported by those of other workers. The appearance of an ocular palsy, heralding itself by the sudden onset of double vision, is a grave omen at best. In the absence of diabetes or trauma, it generally signifies beginning obliterating endarteritis in the carotid system of vessels. Sudden fleeting palsies of a few days duration occurring at intervals of a few months or years are almost invariably the warning signals of locomotor ataxia or general paresis. Formerly they were called rheumatic for want of a better pathology, but to-day we know more of what they mean.

Finally, tertiary lesions may appear in the lacrimal sac as extensions of similar lesions in the nose and accessory sinuses; and also in the lids as ulcers or broken-down gummas. Gumma of the iris is somewhat rare, but sometimes offers a classic picture of this phase of syphilis.

Hereditary Syphilis commonly affects the cornea in childhood and young adult life, although the ocular muscles are also sometimes hereditarily involved. Interstitial keratitis is the form assumed by this phase of the disease. A tendency to run its course is the most marked characteristic of the affection. The flat nose, bluish gray-white corneas, mouths with scarred corners, depressed cheek bones and imperfect teeth make this a clinical picture that should be relatively easy of recognition. Deafness due to inflammation of the auditory nerve and its terminals is a frequent accompaniment of the ocular lesions. Indeed, Jonathan Hutchinson asserts that notched teeth, bluish scarred corneas and deafness make a trinity on which the diagnosis of hereditary syphilis may be based in nearly every case.

Inasmuch as syphilis generally attacks the eye savagely without regard to the tissue involved, patients as a rule appear in the early stages of the disorder, affording opportunity for prompt medication, and the results of the treatment of syphilitic eye diseases are therefore usually very gratifying. Moreover, the ease with which the effects of the treatment may be daily studied and seen makes the treatment of ocular syphilis peculiarly satisfactory. Necessarily the caprice of the ophthalmologist will decide what form of mercury shall be exhibited, but whatever method be employed, one thing is certain; that is, that the pilocarpine or sweat cure will tremendously assist the efficiency of whatsoever of antisyphilitic remedies may be resorted to.

DIAGNOSIS AND TREATMENT OF SYPHILIS OF THE CENTRAL NERVOUS SYSTEM.

BY LUTHER C. PETER, M.D.,

OF PHILADELPHIA;

INSTRUCTOR IN NEUROLOGY, MEDICO-CHIRURGICAL COLLEGE; ASSISTANT NEUROLOGIST TO THE PHILADELPHIA HOSPITAL; CHIEF OF NEUROLOGICAL CLINICS, MEDICO-CHIRURGICAL AND ST. CHRISTOPHER'S HOSPITALS, PHILADELPHIA.

A SHARP dividing line should be drawn between the immediate and remote effects of syphilis of the nervous system. The first is the result of direct action of the luetic virus, and the second is due to organic changes which follow long after the infection has disappeared. In this paper we have to deal only with the immediate infection, the symptoms of which make their appearance usually from six months to two years after the initial lesion, although they have in some cases appeared later.

Ayers (*Pennsylvania Medical Journal*, August 1903, p. 565) classifies the underlying pathological conditions of brain syphilis as (1) a localized meningitis leading to thickening and infiltration, (2) inflammation of the arteries leading to thrombosis, (3) gummatous deposits or tumors and (4) degeneration of nerve structures. Gummatous growths and tumors rarely offer difficulty in diagnosis, producing symptoms which are characteristic of new growth in the brain or cord. The history of a chancre or without this history, the rapid onset and the therapeutic test easily determine the nature of the growth. Thrombosis of arteries and meningeal thickening ofttimes furnish a group of symptoms which are not easy to diagnose. Given the history of infection, the multiplicity of symptoms and the absence of systematically arranged symptoms are features upon which one can place much confidence. In looking over my records and those of the Medico-Chirurgical Hospital, I was unable to find two cases which were exactly alike even in some of the essential points, except perhaps in the distribution of the palsies which usually are hemiplegias or monoplegias.

Paralysis of the cranial nerves, when there is no history of traumatism, is a third factor in favor of syphilis. The fifth and seventh pair are most apt to escape, whereas the sixth is usually involved. In fact, so often is paralysis of the sixth due to syphilis that some authorities regard it as almost invariably due to luetic infection. Willot (*l'Echo médical du Nord*, April 19, 1903, p. 183), however, reports 15 cases of paralysis of the external rectus which were due to influenza, and he believes that we are too apt to regard paralysis of the sixth as always syphilitic. The fact remains, however, that in a great majority of cases syphilis furnishes the virus, and when cranial nerve palsies are found associated with other symptoms of "nervous syphilis," it is strong presumptive evidence of the nature of the trouble. By way of illustration:

Case I.—C. F. H., aged thirty-five years, had a chancre about eight months ago, followed by a profuse eruption. He now complains of head-

ache, vertigo, double vision and drooping of the right upper eyelid. Examination reveals ptosis of the right upper eyelid, marked rotation of the right eyeball upward and outward, inequality of pupils (the right larger than the left) increased deep reflexes and an exalted mental state and a loquacity in excess of his usual habit. The case is clearly one of syphilis of the brain and the eye phenomena furnish strong corroborative evidence.

Inequality of pupils is found in a large number of cases, probably in two-thirds, but in itself is of little value, since it is a common symptom in brain and cord disease. It is, however, of value when associated with other symptoms. Of more importance is irregularity in the pupillary border, which when present points to an old syphilitic iritis. It is of especial value when a history of infection is denied by the patient, for usually it implies the existence of syphilis at some time. It is a local condition, not connected with the nervous system, and only is a guide, not always infallible, but usually of very great help.

Apoplectoid and epileptiform attacks are frequent and their significance may easily be overlooked. Such attacks may come on suddenly, without warning, or they may be preceded by a numbness in one or more extremities, and after the unconsciousness, the patient may in a little while be himself again or parts of the body may be paralyzed. Attacks of unconsciousness or convulsions may be the first warning of the patient's condition or they may only be an incident in or a part of a group of symptoms already existing. In the latter event their presence but adds confirmatory evidence to a diagnosis already made. The appearance of attacks of unconsciousness or convulsions in an adult apparently healthy previous to their advent, should call forth a most careful search for a history of syphilitic infection and other symptoms corroborative of brain syphilis. Some authorities regard epileptic seizures which develop after thirty years of age as almost invariably caused by syphilis. This is hardly borne out by statistics, but the fact remains that a large number at least are syphilitic in origin. On the other hand, fainting attacks in an apparently healthy man, are so unusual that the gravity of the underlying cause is forced upon the physician. By exclusion of other causes, syphilis will be found in many cases, and other symptoms, if diligently searched for, may confirm the diagnosis. A case in point is that of

Case II.—M. S., aged forty-three years, who had a chancre some months before the nervous trouble began. At the time of his first visit he had been ailing for seven weeks, complaining of a pain in the right leg so severe as to keep him awake at night. Sept. 12, 1901, some weeks later, he complained of a "sudden stopping of the heart," feeling as though it had ceased to beat, became faint but was not unconscious. He was carried home and put to bed. Since then he complains of a weight in the right arm, and attempts to write, cause cramping of the fingers. Nov. 21, 1901, two months later, as he was about to get up in the morning, he noticed black spots before his eyes, and then became unconscious. He now has diplopia, slight paresis of right side, increased knee-jerks and marked depression of spirits. Cardiac and renal functions are normal. In this case the apoplectiform attacks are the dominating feature and, together with the history of chancre make the diagnosis quite positive.

Instead of recurrence of attacks of unconsciousness and convulsions, one may have recurrent temporary palsies, and recurrence of palsies is a most characteristic symptom of syphilis, whether of the brain or cord. When due to brain lesions they usually are monoplegias or hemiplegias, and, as a rule, are not accompanied by unconsciousness. In fact, a monoplegia or hemiplegia, gradual in onset, without unconsciousness, accompanied by spastic reflexes on the affected side, and showing a tendency to improvement with subsequent relapse, is, almost without exception, syphilitic and due to a thrombosis of a cerebral artery. A good example is

Case III.—G. L., sixty years old, infected by syphilis six months previous to onset of present trouble. He awoke one morning to find a "feeling of pins and needles" and a weakness in his left arm. During the following three days the arm gradually grew weaker but not absolutely paralytic. Three weeks previous he had much headache. We found him to be well nourished, his chest and back covered with numerous copper-colored scars, pupils equal, moderately dilated, responsive to light and accommodation; all movements of the left arm were weak but not entirely lost, biceps tendon and knee-jerks on the left were spastic and all muscle-jerks and deep reflexes on the right were increased. Under antisyphilitic treatment the arm improved.

Somnolence is a symptom of great value in the diagnosis of brain syphilis, being present in a majority of the cases. It is of especial value when associated with other evidences of syphilis of the brain.

Mental changes are observed in many cases but they are not diagnostic in themselves. The psychoses vary from slight changes, a feeling of well-being and self-satisfaction, to maniacal and melancholic outbreaks. The subject of mental state is too comprehensive to admit of discussion in this paper.

To sum up briefly, variability in symptoms, absence of systematic grouping of symptoms, paralysis of cranial nerves, Argyll-Robertson pupils, irregularity of pupillary margin, inequality of pupils, apoplectiform and epileptiform attacks, recurrent palsies usually without loss of consciousness, numbness in extremities, increased reflexes, headache, vertigo, somnolence and altered mental states, are symptoms which point to syphilis of the brain and its coverings.

It is impossible to differentiate, in so brief a paper, between this condition and other diseases. Suffice it to say, however, that paresis, with which

this condition may be confounded, may be distinguished by its making its appearance quite late, ten or more years after the first infection, and by the early appearance of mental symptoms which usually precede the motor phenomena.

In syphilis of the cord we have a distinct group of symptoms, first described by Erb, characterized by a slowly oncoming spastic paraplegia, atrophic at times, contractures of the muscles, with involvement of the bladder, slight disturbance of sensation, with a tendency to improve and again relapse. The essential point is the widespread involvement of the entire cord, more extensive, however, in one region than another, giving rise to complete loss of function in certain parts and preservation in others. Without even the history of a chancre, a diagnosis of syphilis of the cord may be made, especially when brain symptoms are present, which is usually the case. A case which illustrates typically disease of the brain and cord is that of

Case IV.—D. B., whom I had under observation for about six years. He was thirty-nine years old, and his first symptom developed several years after the appearance of the chancre. He first complained of recurring numbness in one or more extremities, some loss of control of bladder and occasionally of the rectal sphincter. Some months later he rather suddenly lost power in the left leg and partially in the left arm but was not unconscious. He had headache and vertigo and at times had difficulty in speech (motor aphasia), which passed off as quickly as it came. Diplopia was present throughout. Examination revealed a spastic palsy of the left leg and a partial palsy of the left arm, a spastic knee-jerk on the left and an absent knee-jerk on the right, ataxia in the left arm, ptosis of the left upper eyelid, the right pupil oval and contracted, the left irregular and dilated. Sensation to touch was present but he could not distinguish heat from cold and could not always recognize a pin prick. He had the classic Argyll-Robertson pupillary phenomenon and paralysis of the left external and superior rectus muscles. With the ophthalmoscope the right eye showed a low grade of optic neuritis and the left beginning optic atrophy. Four years later he was bedridden and otherwise about in the same condition as above described. His mental state was good but he had difficulty in speech at times. With slight improvement and again exacerbations, he continued in much the same condition for six years and finally died from pneumonia. A post-mortem examination showed, in addition to the pneumonia, syphilis of the brain and cord and their coverings and a chronic nephritis.

It is true that not all cases of syphilis of the cord are as typical as the above case or of the type described by Erb, but the essential feature is usually present, namely a widespread but irregular involvement of the cord.

Little can be added to the approved treatment of to-day. Potassium iodide and mercury do all that drugs can do when administered properly. The best method is the intermittent use of both drugs. Inunctions (the ideal method of administering mercury) may be used twice daily until the physiological effect is reached, either alone or with ascending doses of potassium iodide. After a mild gingivitis is produced, mercury may be withdrawn, and the iodide continued alone for a period, after which inunctions may again be instituted. In spinal syphilis, especially, should treatment be continued at intervals for several years because of the great tendency to recurrence.

The hypodermic administration of mercury has little to commend itself, and the annoyance of abscesses and danger of consequent gangrene, render this method inferior to the administration by inunctions.

THE RECOGNITION AND TREATMENT OF SOME OF THE PHARYNGEAL LESIONS OF SYPHILIS.

BY LEWIS S. SOMERS, M.D.,
OF PHILADELPHIA.

As the pharynx is the most common local site of the various manifestations of syphilis and as the lesions of this disease are seen here in one form or other in the vast majority of syphilitic patients, it is desired at this time to call attention to the more prominent features indicative of the presence of but three of these lesions, namely, the erythema; the mucous patch; and the ulceration, and to briefly outline the form of treatment which has proven most successful in my hands.

Syphilitic erythema as a secondary manifestation of the disease, may be, and I believe often is, mistaken for catarrhal pharyngitis or tonsillitis. The subjective symptoms in many cases are essentially the same and as in private practice the question of syphilis is not usually considered in what appears to be a simple case of subacute pharyngitis, it is probable that many errors are thus committed and the disease proves rebellious to a form of treatment that is not at all indicated. An objective examination of the pharynx should, however, make the diagnosis perfectly clear in the great majority of cases, and under such circumstances the erythema is usually symmetrical, being limited in outline by abrupt, well-defined margins from the healthy mucosa; the contrast at times being most striking, as the patch of congested tissue may be limited to but one pillar, or involve an entire half of the soft palate, stopping in the median line by a limit as if made with mathematical precision. While the color of the affected area is not always characteristic, yet it differs from that of simple erythema, inasmuch as it presents a deeper brick-red or more of a copper hue, and as a further characteristic there is a marked tendency to the development of small irregular patches of cloudy swelling of the epithelium, in this form being shown by linear semi-translucent areas or minute irregular shaped patches.

When these areas of epithelial change become larger, well defined and present a whitish or bluish-white color, they then constitute the second

phase of syphilis, which it is desired to consider—the so-called mucous patch. These are constantly found in cases where the pharynx is involved, and while they may appear anywhere on the mucosa of this region, yet their most constant site is upon the soft palate, pillars and tonsils. Oval, circular or stratiform in shape, they present a slight elevation upon the somewhat swollen and hyperemic mucosa and partake in their symmetry of the disposition of the erythema in this respect. This specific manifestation is practically characteristic and it is hardly possible for one not to recognize it, although it has been confused with herpes of the pharyngeal mucosa; the latter is quite rare however, is attended with considerable pain and consists of groups of broken down vesicles with detached epithelium. In addition to the presence of the mucous patch upon the site previously mentioned, it is also commonly seen where irritation exists, especially at the sides of the tongue and either here or on the buccal surface in the immediate vicinity of a diseased tooth.

While both the erythema and mucous patch present a degree of considerable import on account of their early appearance and thus by their presence enabling one to prevent further and more serious phases of the disease, the syphilitic ulceration is far more fraught with danger to the patient and its early recognition is essential in order to prevent tissue destruction that may seriously endanger life. The areas of tissue disintegration at first shallow, cover a wide, irregular surface and rapidly cause the soft tissues to melt away, while the affected parts are covered with a thick, muco-purulent, offensive secretion. Unlike other affections seen here, the tendency to disintegration and perforation of bone is most marked, and with but little or no pain a large, ragged opening may be rapidly produced between the oral and nasal cavities; osseous destruction being especially marked when an ulcer occupies any portion of the palate. This tertiary phase of syphilis resulting from the breaking down of the gummatous deposit can rarely be mistaken for other pathologic changes in this region, although under such circumstances the question of tuberculosis, lupus and carcinoma rarely may enter into the differential diagnosis, while in a few cases I have seen tertiary ulceration of the tonsils treated for several weeks as well-marked cases of diphtheria. As carcinoma and lupus of this region without manifestations elsewhere are extremely rare and as a tuberculous ulceration of the pharynx of such degree as to at all simulate syphilis would be accompanied with prominent laryngeal and pulmonary symptoms, it seems unnecessary to further indicate any material differences here, while diphtheria can always be recognized by the presence of the specific organism and any confusion between the two diseases can only be the result of gross carelessness.

Three of the most important factors, however, in the recognition of pharyngeal syphilis remain to be mentioned, and while the local lesions in themselves often are sufficiently characteristic to be readily recognized, yet in order to be perfectly secure in the diagnosis, evidence of one at least of these factors should be obtained. I refer to the history of the initial infection, the examination of other portions of the body for evidences of the disease, and finally the results obtained by specific treatment.

As is well known, it is often impossible and frequently not advisable to obtain the history of the primary infection, as in those cases where the question is asked in regard to a primary sore, its presence is usually denied or in late cases of tertiary ulceration, the patient may be perfectly sincere in denying its former presence. A negative history is therefore of but little value and if the local lesions are not sufficiently characteristic, dependence must be placed upon the two other factors mentioned.

In both the erythema and mucous patch, examination of other parts of the body will, in the vast majority of cases, reveal the scar of the chancre, the dermal eruption will be well marked, or in case the latter has faded away, some discoloration in more or less symmetrical areas will usually give a clue to the nature of the throat lesion, while in many cases of tertiary ulceration with both these factors indistinguishable, dependence will have to be placed upon the postcervical glandular swelling, and, if present, of the nodular swellings over the tibia region.

While tuberculosis is usually affected adversely by antisyphilitic treatment, yet pharyngeal carcinoma for a week or two may present some slight improvement under such conditions, but this is transient and in some cases, especially of tertiary ulceration, it is almost impossible to be assured of the diagnosis until the favorable results of specific treatment have been observed.

While both local and general medication have their place in the care of the syphilitic patient in whom the pharynx is involved, yet the latter is of far more importance and many cases in my experience receive no added benefit from local applications. For the erythema mercury is essential, and usually the protiodide in one-quarter to one-third grain doses two or three times daily, will rapidly cause this symptom to subside, while in occasional cases an astringent gargle such as that composed of rhus glabra will accelerate the disappearance of the congestion.

The same form of mercury has also given me the best results in the treatment of the mucous patch, but often the area of epithelial degeneration proves most rebellious to treatment and the occasional application of a 20 to 50 per cent. solution of nitrate of silver will be of material aid, while in other cases the silver salt will apparently be of no value at all and then chromic acid applied locally by moistening a few crystals on the end of an applicator tightly wound with cotton, will often cause the rapid disappearance of the patch. In the mucous patch seen well on during the early tertiary stage of syphilis, mercury will often not only be of no benefit, but will in a

few cases apparently aggravate the condition. Under these circumstances three to five-grain doses of potassium iodide will usually produce marked relief, and the necessity for local treatment either with mineral astringents or caustics will be obviated.

The indications for treatment of the tertiary syphilitic ulceration demand most active measures, as the tissues break down almost within a few hours and serious if not fatal consequences must necessarily ensue, unless the destructive process be checked within a very short time. Iodide of potash should be immediately exhibited in from 15 to 20 grain doses, three times daily and increasing the amount by five-grain doses until a favorable action upon the syphilitic process is observed or tolerance has been reached. Frequently one, two or three hundred grains daily will be necessary and the amount used should depend entirely upon the result obtained. At the same time mercury in the form of the bichloride or protiodide should also be administered and in severe cases, especially when the osseous tissue is beginning to break down, it should be given either by hypodermic injection or inunction. Locally, necrosed bone should be removed when it has separated from the surrounding tissues, exuberant granulations controlled, and a cleansing antiseptic mouth-wash may be ordered to remove the purulent débris.

NEW STAIN FOR DIPHTHERIA BACILLI.

BY EDUARDO ANDRADE, M.D.,
OF JACKSONVILLE, FLA.:
BACTERIOLGIST STATE BOARD OF HEALTH OF FLORIDA.

Though Löffler's blue properly employed gives as a general rule very satisfactory results in the staining of the *Bacillus diphtheriæ*, it is an acknowledged fact that in some cases it fails to bring out the methachromatic granules which play such an important part in the diagnosis of this microorganism; the same is true of Roux's and other stains commonly used. Neisser's stain shows the granules well, but, unless used with a good deal of care, it also fails in many cases. This is especially the case when staining smears made directly from throat exudates.

While experimenting with Romanowsky's chromatin stain for malarial parasites prepared with Borrel's blue instead of Höchst's, it occurred to me to try Borrel's blue in the staining of the *Bacillus diphtheriæ*. Borrel's blue is prepared by the dissolving of a few crystals of silver nitrate, about four grams, in 50 c.c. of distilled water and adding 100 c.c. of normal caustic soda solution. The black precipitate which is formed is washed several times in distilled water and then added to 250 c.c. of saturated water solution of Grubler's methylene blue. The mixture is placed in the incubator at 37° C. during eight days and then decanted. The solution has a deep violet color.

I used at first Borrel's blue in several strengths; then I combined it with vesuvin. A mixture prepared according to the following formula gives very good results:

℞ Borrel's blue ..... 1 c.c.
Vesuvin, watery solution, 1/100,000.... 50 c.c.

The vesuvin should be dissolved in boiling water.

Diphtheria bacilli stained with this solution show the metachromatic granules much better than with Löffler's blue, and this mixture does very well for specimens with a large number of diphtheria bacilli, but when these are scarce and other throat organisms are abundant, it is sometimes difficult to find the characteristic bacilli. For this reason I have devised a method of staining by means of which all other bacteria usually present in the throat with the exception of yeast cells and some large non-identified cocci, are decolorized, the bacilli of diphtheria appearing as pale blue rods with deep reddish-brown granules, in the almost colorless field.

The method of staining is the following: Prepare films in the usual way: (1) Borrel's blue, 5 minutes; (2) wash in distilled water; (3) Lugol's iodine solution, 1 minute; (4) wash in distilled water; (5) decolorize in absolute alcohol until no more blue is given off; (6) wash in distilled water; (7) dry and mount.

The smears should be thin and evenly spread, otherwise the decolorization will not be uniform. The best results are obtained with cultures from eighteen to twenty-two hours old, grown at 37° C. Cultures grown above 37° C. do not stain so well. Smears prepared directly from the swab stain very characteristically, so that the disease can be often diagnosed by staining smears from the throat exudate.

MEDICAL PROGRESS.

MEDICINE.

Volumetric Estimation of Sugar in Urine.—A new method of rapidly determining the amount of glucose in urine is published by E. Riegler (Münch. med. Woch., Feb. 2, 1904), and is destined to come into common use. It is based upon the fact that glucose is oxidized in the presence of permanganate of potassium with the formation of carbonate of potassium and carbon dioxide. By adding sulphuric acid, gas is liberated from the former and can be measured with the latter in a specially constructed apparatus. By subtracting a definite figure corresponding to other oxidizable substances in the urine and by consulting a table with due regard to the temperature and atmospheric pressure, the percentage of sugar can be readily determined with considerable accuracy.

Influence of Trauma in Movable Kidney.—Among the many etiological factors in the production of this condition, trauma has been assigned an important place. M. L. Harris (Jour. Am. Med. Ass'n., Feb. 13, 1904) has examined a large number of cases of railroad injuries, and among about 1,300 there were 41 instances in which this question arose. In about one-half there was a characteristic form of the body with contraction of the middle zone, which the author believes is an important element. After a careful analysis of these cases, he concludes that not in a single one was it certain or

probable that the kidney was made movable by the accident. Movable kidneys occur in women with a particular body form and practically all who possess this have movable kidneys to a greater or less degree. The author also believes that movable kidney is not produced immediately, but requires time for its development. While it is possible to injure, crush or suddenly displace by violence a normally fixed kidney, such displacement is always accompanied by a laceration of the perineal tissues, which is manifested by distinct local and general symptoms. Severe injuries of this kind are seldom or never followed by movable kidneys. Finally, a movable kidney is never the result of a single trauma.

Tendon Reflexes in Uremia.—Although uremia has been pretty thoroughly studied, no great attention has been given to the condition of the reflexes in reference to the diagnostic significance of the excess of excitability, which is undoubtedly present to a remarkable degree. W. M. Stevens (Brit. Med. Jour., Jan. 16, 1904) states that his attention was first directed to the subject by seeing a patient suffering from well-marked uremic coma, present, besides exaggerated knee-jerks, ankle-clonus, knee-clonus, wrist-jerk and elbow-jerk. Although these reflexes are not by any means always present in uremia, the symptom is common and under certain circumstances, it may prove of diagnostic value. In differentiating cerebral hemorrhage, which may begin with a convulsion and may be unassociated with any evident paralysis, and which not infrequently is the result of granular kidney in which case the information obtained from the urinalysis is defective, the author believes that an examination of the deep reflexes might often prove of much assistance, for if one found exaggerated knee-jerks and ankle-clonus with perhaps other signs of great myotatic irritability, a diagnosis might be made. An absence of the signs, however, should not negative the affection. In certain convulsive attacks such as epilepsy, there may be difficulty in differentiating uremia. Here again the exaggeration of deep reflexes may prove helpful. Bevor has pointed out that immediately after epileptics fits, the deep reflexes may be exaggerated. his condition, however, lasts but a few moments, whereas in uremia, if present, it is apt to be permanent. Furthermore, the presence of deep tendon reflexes may be of great service in prognosticating the advent of uremia if they are found present in a case suffering from dyspnea, sleeplessness, headache, vertigo and vomiting, and enable one to forestall the attack.

Physiological Albuminuria.—The question of the importance of hyaline casts and of albumin appearing in the urine of apparently normal and healthy persons is one deserving of the keenest and most careful consideration. Samuel West (Lancet, Jan. 16, 1904) states that cases of albuminuria fall into two groups, depending upon whether the cause lies in the kidney itself or not. In the latter case the cause may be found in the heart or in abnormal conditions of the circulation, in blood changes or other general conditions. In a third group of cases, the urine is normal when secreted, the albumin being added to it as it passes from the kidney to the exterior. Statistics showing the frequency of albuminuria in the apparently healthy differ very widely, the out-patient practice yielding a percentage of from one to three. In conclusion the subject is summed up by the author as follows: (1) Albuminuria may occur as a transitory symptom in persons who, except for this symptom, may be judged to be perfectly healthy, for they appear to be so at the time and remain so. (2) But it may also occur in persons who, though they appear at the time to be healthy, develop signs of disease subsequently. (3) It is difficult to distinguish at a given time between those who will remain well and those who will not. (4) It is difficult to exclude for certain many of the pathological causes to which the albumin might be due. In other words, though there may be no proof that these causes are present, there is equally no proof that they are absent and in some cases the result shows that they were not absent. (5) Speaking generally, the larger the amount of albumin in the urine and the longer it persists the greater the probability of some permanent disease. (6) Continued observation of these cases shows that the so-called physiological albuminuria does very appreciably increase the risk of life, and that this risk grows rapidly with every year of age after thirty years.

Chronic Cyanotic Polycythemia, with Enlarged Spleen.—The chief symptoms of this little known condition are constipation, headache, vertigo and weakness, although good health is not by any means incompatible with a very intense cyanosis. William Osler (Brit. Med. Jour., Jan. 16, 1904) reports that he has been able to collect from the literature six cases in addition to the three which he presented at the meeting of the Association of American Physicians in May, 1903. Six were males and three females; the youngest was thirty-five years of age. The cyanosis was a most remarkable feature without any dyspnea and without obvious cause. The blood viscidity was greatly increased, unusually dark in color, and in eight of the cases, the red blood cells were above nine millions to the cubic centimeter. The hemoglobin ranged from 120 to 150, the leucocytes showing no special changes. In seven of the nine cases the spleen was enlarged, in four reaching nearly to the navel. In five of the cases pigmentation of the skin was marked. There were necropsies in three of the cases. In Cabot's case the patient died comatose with cerebral hemorrhage. In Stockton's case, the heart was normal, there was moderate emphysema of the lungs and splenic enlargement. In Saunby and Russell's case there was hypertrophy of the left vessel and great enlargement of the spleen. The possibility of the condition being due to miliary tuberculosis of the spleen has been suggested by Rosengarten. Cyanosis and polycythemia are met with in primary tuberculosis of the spleen, but it does not seem at all likely that the cases of cyanotic polycythemia are due to this cause. This belief is substantiated by the results of three autopsies in which no mention is made of caseous masses or miliary tubercles in the enlarged spleen, and moreover, the chronic course—eight or ten years in some cases—is opposed to it. It is important in studying cases of obscure cyanosis to bear in mind the possibility of chronic poisoning with the coal-tar products.

SURGERY.

An Early Symptom of Severe Appendicitis.—There is no absolute symptom which will differentiate mild from severe cases of appendicitis during the onset, hence early operation in all cases is coming more and more in favor. L. Moszkowicz (Münch. med. Woch., Jan. 26, 1904) draws attention to the fact that the serious cases are generally characterized by the presence of a serous effusion in the abdomen. If all cases be systematically examined for fluid, it may be possible to divide them into those which require operation at once, and into those where delay does not matter. The best way to determine fluid is to place the left index-finger and thumb, spread apart as far as possible, upon the abdomen, and to percuss with the right middle finger upon the former, gradually approaching it to the thumb.

Operative Treatment of Tumors of the Nasopharynx.—This subject is fully discussed by E. Payr (Archiv f. klin. Chir., Vol. 72, No. 2), who presents the following conclusions: He believes that Kocher's method, which includes the osteoplastic resec-

tion of both superior maxillæ, offers the most complete exposure of the nasopharyngeal space, and is superior to the preliminary operations formerly practised. Such a complete exposure of the operative field offers the best chance for the radical removal of the growth, particularly if the latter be malignant. The technic of the procedure is not particularly difficult, when compared with the nasal, maxillary and temporal methods formerly practised. One of the great advantages is the slight degree of disfigurement caused. The functions of the parts involved are also very little disturbed. Patients usually stand the operation well and the dangers from hemorrhage and aspiration may, with proper precautions, be reduced to a minimum. He recommends that the operation be done with the patient's body at an angle of forty-five degrees, and the head allowed to hang over the upper edge of the table. Preliminary tracheotomy and the preventive ligature of both external carotids then become unnecessary. The author also suggests that where the choice of an operation depends on the vascularity of a nasopharyngeal polyp, the examination should be conducted with the head hanging down. The modified position has been used by the author with great success, not only in this, but also in other operative procedures in the nose, mouth or pharynx.

Relief of Various Forms of Hernia.—According to O. Horwitz (Proceed. of Phil. County Med. Soc., Jan. 30, 1904), the safety of the patient, as well as the lowering of the mortality in strangulated hernia depends on gentle taxis being exerted for a short period, which, if unsuccessful, should be succeeded by an immediate operation. Herniotomy in the aged is not a dangerous operation, provided it is performed as soon after the constriction has taken place as possible. An inflamed hernia should not be treated by taxis, but by operation. No one method of attempted radical cure is applicable to every variety of rupture. The Bassini is suitable to the largest majority; the Bloodgood for those in whom a large abdominal ring and weak or atrophied conjoined tendon exist. The relief of special forms and conditions must be met by the ingenuity of the surgeon. The palliative operation is applicable to a large number of selected cases of reducible hernia, when the protrusion cannot be kept within the abdominal cavity by means of a truss, and also in some cases of incarcerated hernia. A radical cure may be safely attempted on patients who have reached their sixth year, and on those who have arrived at their sixtieth. Individuals who submit to the palliative operation should continue to wear a truss after recovery. In cases not applicable to a routine method, the best means of removing the entire neck of the sac on a level of the parietal peritoneum should be used. Then the opening in the peritoneum must be firmly closed, the depression of the peritoneum in the vicinity of the internal abdominal ring obliterated, the structures brought into apposition, and the apertures closed which form the canal through which the rupture protrudes. An aseptic result is necessary for a permanent cure. In cases of undescended testis, every effort should be made to save the organ. The method of operating for umbilical hernia, suggested by Mayo, is probably the most satisfactory. Absorbable sutures are preferable in all cases.

Gall-bladder Surgery.—It had seemed from the recent publications of Kehr and of others that one of the greatest advances in surgical technic was the extirpation rather than the simple drainage of the gall-bladder. This conviction will be rudely shaken by an article of Maurice H. Richardson (Bost. Med. and Surg. Jour., Feb. 11, 1904), which might almost be called "cholecystostomy vs. cholecystectomy." The paper is based on 200 operations, and many additional observations. As regards the dangers of the two operations, the author is of the opinion that in unchanged or in slightly changed gall-bladders, they may, in the hands of experienced operators, be considered very slight; on the other hand, in the case of thickened, contracted, adherent, gall-bladders, the dangers of either operation are very considerable. Leaving aside the element of danger, then, which perfection in technic tends to render more and more equal, the operations may be compared as to their immediate and remote effects. Richardson is of the opinion that "drainage of the biliary passages is the one great benefit to be gained by the operation on the biliary passages, whatever may be the lesion for which the operation is undertaken." If now, the gall-bladder be excised, drainage must be performed through the hepatic duct. This necessitates a far larger incision and longer operation, a much less copious drainage, and imperils the subsequent integrity of the ducts through the danger of ulceration, necrosis and cicatrization. It seems logical to conclude, therefore, that cholecystostomy is preferable to extirpation. As regards the remote effects, the chief question to be considered is that of reformation of stones in the diseased gall-bladder. The author is firmly of the opinion that stones are practically always formed in the gall-bladder and never in the intrahepatic ducts; it is a tempting prospect, therefore, to remove the *fons et origo mali.* Clinical experience, however, has taught him that only in the rarest instances are gall-stones reformed either in the bladder or the duct after cholecystostomy followed by a period of drainage. The argument seems, therefore, overwhelming in favor of cholecystostomy, and against extirpation.

Genito-urinary Tuberculosis.—Honesty and thoroughness are the earmarks of the work done in the Johns Hopkins Clinics, and these qualities are conspicuous in a recent article on genito-urinary tuberculosis by Guy L. Hunner, assistant in the Hospital to Prof. Kelly (Bull. Johns Hopkins Hosp., Jan., 1904). The report is based on 35 cases, all of which were operated on. The average age of the patients was 31½ years, showing that the disease is one of young adults. The previous history revealed that four of the cases had had earlier symptoms of tuberculosis in other regions—joints, glands, abdomen, or lungs. Within the genito-urinary tract itself the infection is generally primary in the kidneys, as shown by the clinical and pathological findings. Nevertheless, it is a striking fact that in fully one-half of the cases the earliest characteristic symptoms are produced by the bladder, owing to the secondary infection of that viscus. The disturbances and symptoms due to tuberculosis of the kidney when confined to that organ are generally vague and difficult to recognize. The disease may easily be confused with malaria or typhoid, on account of the general symptoms and the temperature curve, or with appendicitis, gall-stone colic, movable kidney (Dietel's crises), and so forth, on account of the subjective symptoms. "Any symptoms referable to the urinary tract" may mask a true renal tuberculosis. The diagnosis depends on the palpation of the enlarged kidney through the abdomen, and of the thickened and tender ureters through the vagina. It may be completed by a cystoscopic and bacteriological diagnosis. Opposed to the difficulty in diagnosis, is the comparative ease in treating the cases, provided they present themselves early enough. The entire problem for the surgeon is the extirpation of the infected tissue—kidney, perhaps ureter, or even part of the bladder. The fact that the disease is generally primary in the kidney, and is in the vast majority of cases localized to one side tends to make this effort quite feasible, and gives a good

prognosis for radical operations, as is demonstrated by the records of the cases treated at Johns Hopkins.

Partial Enterocele.—This condition is as interesting as it is rare. Its etiology is still undetermined. Whether it begins from a false diverticulum or always acutely, as in accidental strangulation of some portion of the wall of the small intestine, is an unsettled question. Lucius W. Hotchkiss (Ann. of Surg., Feb., 1904) states that it is a form of strangulated hernia which is most dangerous because of the absence of typical symptoms. The hernial sac is generally small; its contents, a portion of intestinal wall or, rarely, omentum. Under the typical conditions of small aperture and unyielding margins, the strangulated portion of the gut wall soon loses its vitality, and perforation and peritonitis may ensue before the case assumes characteristic evidences of gravity. Although occasionally a typical hernia may have existed, most frequently the lesion consists in a very small, often unnoticed swelling which after an unusual exertion becomes painful. There can of course be no intestinal obstruction in the early and dangerous portion of the disease Pathologically it is usually characterized by involvement of that portion of the gut which is opposite the mesenteric attachment Adhesions between the gut and the neck of the sac protect the general peritoneum for a short time, but this barrier to peritonitis is extremely frail. The author then reviews six cases to illustrate the lack of uniformity in the symptoms and the absence of any single pathognomonic sign for early diagnosis, and, finally, the great disproportion between the severity of the earlier symptoms and the real gravity of the case.

Results of Oophorectomy for Mammary Carcinoma.—Although a well-known surgeon has said that he had not the courage nor the faith to propose this operation for inoperable mammary carcinoma, the results of its employment appear to justify the belief that he was in error. G. E. Herman (Lancet, Jan. 16, 1904) recites the recent history of a case which was published in the Lancet six years ago. The carcinoma under discussion was removed in 1890. At the end of 1896 it had recurred, invading the axilla and neck so extensively as to be absolutely inoperable. In 1897 the ovaries were removed. Six months later none of the recurrent growth could be felt. The patient remained in good health for four years when she began to develop repeated sweats and low-grade temperature manifestations. A month later she had an attack of pain in the left kidney so severe as to necessitate the use of morphine Shortly after this she began to suffer from epigastric pain after taking food, vomiting commenced and her feet became edematous. There was no albumin in the urine, nor fluid in the abdominal cavity. Three months later a little blood was present in the urine. Dyspnea became marked, retention of urine subvened and the patient died shortly after. No autopsy was made, but there can be no doubt that she died of recurrent abdominal carcinoma. Whatever criticisms may be made upon the technic of oophorectomy in these cases, it is self-evident that through its agency this woman was granted 4½ years of active and healthful life. The cases in which, up to 1900, oophorectomy has been performed have been collaborated by Stanly Boyd. The broad result which they show is that in about one-third of the cases the patient obtained "more or less marked benefit." This benefit consisting of retrogression of the cancer and a period of a few months or years of good health. This is too much to be accounted for by chance. The objections urged against the operation are three: (1) The immediate risk to life. This, in competent hands, is exceedingly small. (2) The temporary suffering caused by the operation. This is not, however, to be compared with the possibilities of ultimate benefit. (3) The effect of removal of the ovaries on certain functions. This, in the case of a patient doomed to die from carcinoma at no very distant date, is not worth considering. As opposed to these objections the patient can faithfully be told that there is one chance in three that the disease will retrogress and that she will have some months or perhaps some years of good health. It seems highly probable that the future of the operation is assured.

PHYSIOLOGY.

Physiological Action and Solution Tension.—The efforts to attribute physiological action to physical rather than to chemical characteristics are strongly supported by the result obtained by A. P. Matthews (Amer. Jour. of Physiol., Feb. 1, 1904), who finds that the poisonous action of any salt is a function of both ions and varies inversely with the sum of the solution tensions of the ions, *i.e.*, with the decomposition tension of the salt. The physiological action of any ion or atom(?) is, hence, determined by its solution tension, or its affinity for its electrical charge. Mercury, silver and copper are poisonous because they part with their charges to the protoplasmic particles easily, thereby bringing about changes in the state of aggregation of the colloidal particles, and decomposition of the molecules, in other words, physical and chemical changes leading to movements, and so on.

The Physiology of Unstriated Muscle.—Of extreme interest in itself and in its general relation to the knowledge of the phenomena that underlie the vital manifestations of the contractile tissues, is the painstaking research pursued for many years by P. Schultz (Archiv f. Anat. u. Physiol., Nov. 27, 1903), and just completed. If the contraction-curve of smooth muscle, such as that from the frog's stomach, be studied, it will be found to graphically represent two processes, contraction and relaxation, both of which are active manifestations. The intensity and speed of the former are increased by increased strength of stimulus, rise of temperature, increased tension, and repetition of stimulus; they are diminished by fatigue, lowering of temperature and reduction of the strength of stimulus. In studying the variations to which the relaxation-phase of the muscle-curve is subject, the author finds that it consists of two parts: In raising the strength of the stimulus it is noticed that after the muscle has reached its height of contraction, the relaxation that follows is at first rapid, represented by a steep line, and then slow and gradual, represented by a line much longer and more inclined. These two stages of the relaxation were separately studied. They represent together antagonistic forces; the first corresponding to the effort of the muscle to return to the norm, the second corresponding to the effort of the muscle to keep up a portion of its contraction. The first would, therefore, be the real relaxation-phase. Its speed is increased by increased strength of stimulus, rise of temperature, increased tension, and overloading; and diminished by reduction of stimulus and of temperature. The second, gradual stage of the relaxation evidently represents a process inhibiting the first rapid stage. Moreover, the original contraction does not fully disappear; there is really left a remnant of the contraction, which is usually described as the condition of tonus. The incidence of this tonus depends upon two factors. First, there is neurogenic tonus, which is the influence normally exerted by the nerves on the visceral muscle. Second, there is a condition of muscular tone which is original in the muscle, which may be termed "substantive" tonus. This latter remains even after the former has been abolished by atropine poisoning. To this original tonic property of the muscle must be attributed the

second, slow, gradual stage of the relaxation-tracing. By means of small weights attached to the muscle for a long time, this tonus may be overcome, but greater weights applied for a long time bring it again into play. Even after the muscular tone has been abolished in the former case, if a maximal stimulus be applied, the muscle will contract and the original tonus will reappear. Similar stimuli applied after this evoke a stronger contraction. It appears that the purely physical phenomena of tension and shortening, through loading and unloading, are bound up with the physiological events associated with the contraction. With the condition of passive tonus the author contrasts the muscle contraction as an active phenomenon, which is bound up with the condition of neurogenic tonus.

The Esophagus in Deviations of the Vertebral Column.—It has been generally supposed that the position of the esophagus was more or less affected by scoliotic or kyphotic displacements of the vertebral column. W. Jawin (Archiv f. klin. Chir., Vol. 72, No. 2) has determined in a number of careful autopsy examinations that this is not always the case. He found that the aorta and other vessels which are attached to the column by their branches, closely follow the bendings of the same. The trachea is affected to a lesser degree. Where the esophagus lies behind trachea and the arch of the aorta it may be bent in the sagittal and frontal planes. Below the bifurcation it leaves the column and passes over the curvature (like the string of a bow). The exceptions are seen in those cases where the connective tissue lying back of the esophagus has become fixed and rigid owing to the action of a pathological process such as a pulmonary tuberculosis or a tuberculosis of the mediastinal glands.

NEUROLOGY AND PSYCHIATRY.

Permanent Cures of Jacksonian Epilepsy.—There were two cases of traumatic Jacksonian epilepsy reported in 1896 as cured by operation done five years previously, which have repeatedly figured as favorable cases in various statistics. A further report is now made by G. Englehart (Deut. med. Woch., Jan. 21, 1904), who states that one of the patients has remained cured to the present, twelve years after operation. The other patient had seizures at long intervals for three years, and was then free for two years. They then came on again and in two years became so severe and frequent that the patient was driven to suicide.

The Relation of Syphilis to Tabes.—An interesting communication on this subject is presented by F. Lesser (Berl. klin. Woch., Jan. 25, 1904), in which he protests against the theory that syphilis is the active agent in the production of this disease. In many cases the patient's statement is alone relied upon in taking the history. Syphilis is very widely distributed, and the same proportion of involved individuals would probably also be found among a series of pneumonia or tuberculous cases. He believes that a more definite anatomical basis should be gained by a sufficiently large number of autopsies in tabetic subjects. Absolute signs of a previous syphilitic infection may be difficult to demonstrate, but the investigation should determine, as far as possible (1) in what proportion of necropsies on tabetics well-marked anatomical evidences of syphilis are present, and (2) in what percentage of all autopsies done in persons over thirty-five years old syphilis can be demonstrated. A comparison of these percentages should lead to some conclusion. Among a series of 96 cases of tabes tabulated by the author, syphilis was definitely demonstrated at autopsy in 27 (=28 per cent.). Post mortems in all other cases over the age of thirty-five years showed syphilis to have been present in 9.5 per cent. This shows that there is a certain etiological relationship between tabes and syphilis in a certain proportion, but not in all cases, for it is by no means proven that every case of tabes was preceded by syphilis. In those cases where there is some connection with syphilis, the question remains whether the disease is directly a syphilitic one, and with what stage of the latter can it be compared? To the secondary and tertiary manifestations, as ordinarily considered, the author proposes the addition of a third class—interstitial inflammations or quaternary manifestations. The latter consist of interstitial proliferations and parenchymatous degenerations of the internal organs, which run a chronic course in the later years of the patient's life, never heal, and do not react to either mercury or iodine. He considers that in the majority of cases this stage succeeds the tertiary gummata, but as it does not cause any symptoms, remains undiscovered during life. The histological changes in tabes consist essentially in parenchymatous degeneration of the nervous elements of the posterior columns of the cord and proliferations of the connective tissue elements, the neuroglia. This interstitial inflammation may be considered the primary pathological process and corresponds closely with the manifestations of the quaternary syphilis already mentioned. The author believes that the various theories advanced against the syphilitic nature of tabes can be readily explained by accepting this proposition. These objections he discusses as follows: (1) It has been claimed that mercury and iodine are without therapeutic effect in tabes, whereas they exhibit a well-marked specific action in the presence of syphilitic lesions. As already shown, however, tabes is neither a secondary nor tertiary manifestation of syphilis, and it is known that the later interstitial inflammations which accompany the form designated as quaternary, are not influenced by either of these drugs. Clinically, however, it is almost impossible to decide in any given case whether the tertiary or quaternary form is present, and the effect of specific treatment should first be tried—in case it fails, to be immediately abandoned, as it otherwise produces harm. (2) In most cases of tabes no evidences of syphilitic disease of the skin or viscera can be detected, and conversely in uncommonly severe cases of syphilis no tabetic affection of the cord can be proven. He explains this by assuming that syphilis is a bacterial contagious disease, as apparently well supported by clinical and pathological evidence. This irritation governs the intensity as well as the intensity of the resulting reaction in the organism. The latter is most effective at the appearance of the secondary manifestations and weakest when the quaternary stage comes on. If the virulence of the infections again persists for a prolonged period, the secondary stage will be extended and the quaternary manifestations correspondingly delayed. For this reason the cases in which marked ulcerations are present, and where the virus remains too virulent to produce merely interstitial inflammation, remain free from tabes. And in those cases where quaternary symptoms appear and the virus is consequently diminished in power, are not afflicted with gummatous processes of the skin and internal organs. These facts are supported by clinical evidence, for the coincident appearance of tabes and tertiary manifestations are of the greatest rarity. In certain regions, moreover, where syphilis assumes a very virulent form, marked by ulcerations and destruction, tabes remains practically unknown. The author also found that in these sections, autopsies rarely disclose the presence of any quaternary evidences of syphilis. (3) Considering the great frequency of syphilis and the comparatively rare appearance of tabes, any connection between the two diseases has been doubted. This contention is not well founded, because we can only

consider tabes as a localization of the quaternary manifestations in the spinal cord. Assuming that among 100 cases of syphilis, tabes occurs only once, this does not deny the syphilitic nature of tabes, for among this same number of cases it may be found that a gumma of the elbow is only present in one. The disease is likely to appear in one than in many localities in its later manifestations. (4) It has been claimed that tabetics are subject to syphilitic infections, and are not immune. It is proven in numerous other instances, however, that persons which present tertiary symptoms may become reinfected and that the immunity against syphilis is a limited one. The delayed appearance of the quaternary symptoms renders the absence of immunity and consequent reinfection even more probable. (5) Finally it has been asserted that tabes is a localized rather than a systemic disease, and that this is contrary to the usually entertained conception of syphilis. Interstitial syphilitic lesions are characterized, however, by their predilection for certain localities in particular organs, in the liver, testis, tongue, and likewise the cord—in the latter instance in the posterior columns. Such manifestations in other organs are considered part of a systemic disease. Why not, he asks, in the spinal cord? Another interesting fact to which the author calls attention is the apparently close connection between tabes and aneurisms. Autopsies in the latter class of cases have demonstrated the presence of syphilis in about 26 per cent., usually in the form of the interstitial, quaternary manifestations. Moreover, among 96 cases of tabes, aneurisms were found in 18—about one to five. He concludes that both lesions are due to the same primary cause, the quaternary lesions of syphilis.

OBSTETRICS AND GYNECOLOGY.

Prolapse of the Placenta.—This condition, where the placenta is normally situated, is quite unusual, and the case reported by F. Kayser (Archiv f. Gyn., Vol. 70, No. 3) is, therefore, of interest. The patient had a markedly rachitic narrow pelvis, but at the first examination no other abnormal conditions were found. Later on another examination revealed the placenta at the os. Assuming that a placenta previa was present, combined version was performed, and the foot pulled down into the vulva. After a period of fifteen hours, during which there were practically no pains, the patient suddenly went into collapse. The cervix was then incised and extraction immediately completed—perforation being necessary in order to deliver the after-coming head. During this procedure the woman died. The uterus was found to be enormously distended with blood, and the autopsy showed that the placenta was normally attached at the fundus. This phenomenon in connection with prolapse of the placenta is very unusual, but serves as an indication of the necessity for immediate ending of the labor in cases of such character. He does not think that version is advisable, and believes that the delay in extracting the after-coming head was responsible for the extreme hemorrhage. The delivery should, therefore, be cranial, using forceps if necessary.

Statistics of Tubal Pregnancy.—Based on a series of 233 cases observed at the Charite in Berlin, E. Runge (Archiv f. Gyn., Vol. 70, No. 3) presents the following views as to the etiology, pathology and treatment of this condition. He thinks that the main etiological factor in the production of a tubal pregnancy is a chronic gonorrhea or a puerperium which has run a pathological course. Nulliparæ do not prove an exception to the process, however. A tubal pregnancy is often preceded by a period of greater or less sterility. Tubal abortions and rupture occur most commonly during the first three months of pregnancy. Operative interference need only be considered (1) when symptoms dangerous to life are present, (2) when there is a distinct increase in the size of the tumor, (3) when the general condition is getting worse or a resorption of the tumor does not take place, (4) when the temperature continues high. The best operative procedure is laparotomy, and drainage of the abdominal cavity should not be practised. Unless distintegration of the coagulated masses of blood has taken place, only those which can be readily reached should be removed. Interference should not be postponed until the fetus has reached a viable age. When hematoceles are present, they should be treated in a conservative manner. Operation is only indicated by particular conditions, and should be done by means of a posterior vaginal section. Laparotomy should be reserved for those cases where the tumor is very large or difficult of approach by the vaginal route.

EYE, EAR, NOSE AND THROAT.

Labyrinthine Suppuration.—An otitis media may spread to the internal ear by way of preformed passages or by new channels, but the most common route is either the fenestra rotunda or ovalis, according to E. P. Friedrich (Münch. med. Woch., Feb. 2, 1904). These orifices are normally protected, but it frequently happens that the operator unintentionally removes the plate of the stapes, or that this bone and the ligaments are completely destroyed by suppuration. The most common sites of artificial communication are the ampullary tubercle of the horizontal semicircular canal and the promontory. In all cases, however, an osteitis results, which spreads unevenly over the greater part of the labyrinth. Round-cell infiltrations are found upon the vestibular side of the stapes, and on the inner side of the membrane of the round window; later connective tissue with lime infiltration will be formed here. Ultimately the endolymphatic system will be invaded, but primary disease here is rare. All the cases observed died of suppurative meningitis, which is best explained by the communication between perilymphatic and subarachnoid spaces, through the aqueductus cochleæ. The sheaths of the acustic nerve may act in the same way, but the endolymphatic duct is of less importance, since the perilymphatic space is always diseased first. Sometimes the meningitis develops through the agency of an extradural abscess, when the labyrinthine caries brings about defects on the inner side of the organ.

THERAPEUTICS.

The Efficiency of Persodine in Phenol Poisoning and Intestinal Auto-intoxication.—The various inorganic sulphates have been administered per os in carbolic acid poisoning with the view of promoting the formation of a non-toxic sulpho-compound of phenol. G. Bufalini (Arch. Ital. de Biologie, Nov. 21, 1903), preparatory to his own investigations in reviewing the results of other experimenters, finds that Marfori has preferred the use of ammonium sulphate administered hypodermically, in order that the ammonia, instead of increasing the alkalinity of the blood, might be eliminated in the urine as urea. The author experimented instead with a substance known as persodine, and found in commerce in the form of small pastilles, which is merely a triturated mixture obtained from the solutions of persulphate of sodium and of ammonium by a special process. This was administered to rabbits hypodermically after a toxic dose of phenol had been given, with the result of overcoming this toxicity. The author alludes in this connection to the researches of Boix and Noe, who found that the prolonged administration of hyposulphite of soda does not attenuate the effect of intraperitoneal injections of phenol, and concluded that this result would

not justify the use of the former drug in cases of intestinal putrefaction, for which it is largely used. The author does not pretend to have proved absolutely the power of persodine as an antidote for phenol, but he claims that this substance, by facilitating the formation of sulpho-compounds, will prove valuable for the neutralization of intestinal toxins (phenol, indol and skatol), which are frequently the cause of serious troubles. Moreover, the alkaline persulphites are valuable aperients, improve the appetite and increase the weight.

New Galactagogue.—Some twenty years ago cotton seed was advocated for this purpose by a number of German observers. More recently Theo. Zlocisti (Berl. klin. Woch., February 1, 1904), has again taken up this subject and presents his clinical experiences. He administered the cotton-seed meal in a purified form and freed from the indigestible cellulose constituents, to twelve nursing women, who had an insufficient supply of breast milk. None of the patients manifested any objections to taking the substance, and no digestive disturbances were noted. The effects became noticeable in from three to four days after the administration was begun, after some 25 to 30 grams had been given. The quantity and quality of the milk was apparently increased, as the infants in question did not require any supplementary feeding. The breasts also increased in size and became distended; a diminution in the supply only occurred after the substance had been omitted for several days. During the later periods of lactation about double the quantity was required to produce the proper effect. This preparation is known as "lactagol," and the author considers that it is a very efficient aid when other hygienic measures fail.

Properties of Lily-of-the-Valley.—It is not desirable to substitute convallamarin for lily-of-the-valley, since D. Laigre (Rev. de Therap. Med. Chir., Nov. 15, 1903) has found that while the tonic action on the heart is about the same with both, the diuretic properties are in great part to be attributed to the fresh convallarin. Unfortunately the drug varies considerably in strength, depending upon the quality of material employed, the use of heat in the manufacture of the extract, and other unknown factors. It is for this reason that a constant pharmaceutical preparation in the form of the juice of the fresh plant is recommended. It contains 2.25 grams of convallamarin and 1.2 grams of convallarin per kilogram; possesses all the physiological properties of the plant itself, and may be employed in doses of 5 to 15 centigrams, gradually increasing by 5 centigrams.

A New Soap for Disinfection.—T. Westhoff (Therap. Monatsheft, Jan., 1904), believes that the only safe soaps for surgical use are those containing some gritty substance for mechanical disinfection. The reason why those on the market are so unsatisfactory is because they contain carbonate of lime, which, when viewed under the microscope, appears as large, irregular crystals with sharp projecting angles that are very apt to produce slight abrasions in which the germs can easily lodge. The new soap has for its base silicic acid which occurs in much finer subdivision and leaves the hands soft and smooth even after prolonged use. Other ingredients are sodium soap, wax, lanoline borax and stearine. Bacteriological examination gave a much greater freedom of germs than with other soaps, and a number of experiments with aniline dyes proved that the upper layers of the epidermis are indeed removed

Theocin as Diuretic.—Theocin or theophyllin and its salts forms a most interesting group of diuretics with purely renal action, and if used properly, must be regarded as a valuable addition to our patent drugs. L. Alkan and J. Arnheim (Therap. Monatsheft, Jan., 1904) can record a truly remarkable flow of urine in all dropsical conditions after the first few doses; it requires only a short time, however, for the renal cells to get accustomed to the drug and soon the same small amounts of urine as formerly are voided. If no other diuretics and cardiac stimulants are given, they will be much more effective than before. The following rules may be laid down: In chronic interstitial nephritis, a varying amount of functionating tissue is still present, especially in the protuberances of the surface. Here it is best to start diuresis with one or two daily doses of theocin and to give calomel or digitalis as soon as the embarrassed circulation is relieved. In general renal congestion, theocin would only increase the beginning parenchymatous degeneration of the cells, hence digitalis must be given first, to allow the cells to recover. In acute inflammations of the kidneys, theocin is decidedly contraindicated. The usual dose is 5 grains every two hours for 3 or 4 doses.

Treatment of Typhoid with Serum.—At the present day, when the most sanguine articles on serum treatment of disease alternate with equally pessimistic ones, a sober, critical article, such as that of D. Du Mesnil De Rochemont (Therap. Monatsheft, Jan., 1904), is doubly welcome. The serum of Jezz, obtained from thymus, spleen, bone-marrow, brain and spinal cord of strongly immunized rabbits was employed, since there is every reason to believe that the antibodies are produced in these organs. Wonderful cures cannot be reported, but the author thinks that in every case the course was modified and rendered milder, though not shortened. The fact that typhoid germs could be cultivated from the blood and that a relapse occurred after large doses had already been given, speaks against a strong bactericidal action. Further tests are, however, necessary, especially in epidemics of varying severity.

Ninety Million Dollars for Typhoid Fever.—In his address on the Water Supply of Cities before the Michigan Municipal League, Dr. Victor C. Vaughan, dean of the medical department of the University of Michigan, pointed out the loss to the country every year from typhoid fever. "There die in this country every year," he said, "from typhoid fever alone not less than fifty thousand people. There are sick in this country not less than five hundred thousand people from this same cause. To get down to dollars and cents, which is the American way of figuring everything, say each man is worth one thousand dollars—and it was estimated in the days of slavery that a man was worth one thousand dollars. It is estimated also that it costs on an average, one thousand dollars to bring a child from the cradle down to the time that he is able to support himself. Say that the average human life is worth a thousand dollars. Then with fifty thousand deaths from this disease, we are losing by death alone, fifty millions of dollars. But there are five hundred thousand people sick. Then we will say that the time of each one of these individuals is worth a dollar a day. Besides that there must be at least one nurse, and we will suppose that these services are worth one dollar a day. Then for each day that those five hundred thousand people are sick, the people of the United States are paying one million dollars. And forty days is certainly an average duration for typhoid fever. Then, with this forty million and the fifty millions loss by death, it is interesting to note that the people of the United States are paying a tribute of ninety million dollars to our ignorance for the existence of a disease which, if every man did his duty, would not exist at all."

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MARCH 12, 1904.

KALK METASTASEN.

It is perhaps a reminiscence of the alchemistic tradition in medicine which ever and again directs the researches of the physiological chemists to the discovery of some vital or essential salts in the body. At one time, quite late indeed in the nineteenth century, phosphorus had become all important: "Ohne Phosphor kein Gedanke," said the German brain physiologists of that day. Still later, iodine usurped the dignity, and pharmaceutical "iodo-" preparations of every variety became legalized. But the most important and interesting phase of this problem has been opened up by the recent investigations and theories of Prof. Jacques Loeb and his pupils, which are too well known to need rehearsal.

Amid the flux and reflux of opinion certain facts stand out with increasing definiteness, and of these not the least remarkable is the significance of the calcium salts in the animal economy. They circulate in the blood; according to an accepted theory they play an essential part in the clotting of that fluid; they enter into the reaction which results in the formation of the acid of the gastric juice; and, finally, in the more subtle vital relations investigated by Loeb they have been found to possess most powerful and peculiar properties.

To the clinician they appear under a variety of forms, chiefly as calculi, or as a part of calculi, in the gall or urinary bladder, and also as the offender in the arteriosclerotic processes of the body. Virchow long ago appreciated the importance of calcium in pathological processes; indeed, one of the most interesting of the many generalizations which he founded was that of the calcium equilibrium, from the pathologist's standpoint, in the human body. This led him to the theory of "Kalk Metastasen," since he observed that in cases of certain forms of bone disease, *e.g.*, tumor, which induced a large amount of bone rarefaction and absorption, calcium salts were laid down in certain viscera of the body which, except under such conditions, practically remained free from them; for example, stomach and lungs.

As may be imagined, this theory has not failed in the course of years to awaken opposition, which has, however, been rather timidly expressed. In the last number of the *Journal of Pathology and Bacteriology* there is a very full and detailed consideration of the whole question by Beer, based both upon the previous literature and much original material. From this article it would seem impossible to avoid the conclusion that "Kalk Metastasen" in Virchow's sense, do not really exist. In other words, the deposition of calcium would seem to be governed by some other factor than its mere excess in circulation. Weigert, it will be remembered, held that lime deposits were caused by purely local conditions, such as low vitality of the tissues. Again, it has been suggested that there is a calcium diathesis, like the supposed uric acid diathesis of the gouty. Be this as it may, the fact remains that the entire problem well deserves to be investigated and ventilated afresh, from a modern standpoint and with modern methods, and this is a work in which physiologists and chemists may share, and from which they may also expect to reap large benefits.

THE EOSINOPHILIC LEUCOCYTE IN SEPTIC INFECTIONS.

Ever since blood examination has become a routine measure in the clinical laboratory the expectation has been general that the diagnosis of obscure septic conditions would some time be rendered less difficult through the discovery of some characteristic factor.

For a number of years an increased leucocyte count was viewed in this light, but very soon it was learned that septic conditions could occur in which the actual number of the leucocytes was

not increased, and that even normally the total number could vary within fairly wide limits. Hyperleucocytosis, to be sure, was the rule, but the surgeons especially were not infrequently confronted with normal and even subnormal counts where operation could definitely prove the existence of suppurative processes. For a while the literature on the value of blood examination in the diagnosis of septic conditions abounded in polemical expositions, in which, on the part of certain surgeons especially, there was very little manifestation of graceful courtesy, and less of laboratory education. It was calmly suggested that the laboratory worker had no place at the bedside.

And what is the result of the strife? The laboratory worker still counts the leucocytes of the patients, but he does more. He makes a differential count, and with the introduction of the differential count a new factor becomes apparent in septic conditions. It is now ascertained that in all septic conditions there is an increased percentage of polynuclear neutrophilic elements and that the mononuclear leucocytes are relatively decreased. The recognition of this fact marks a distinct advance in the clinical value of blood examinations, as the relative increase of the polynuclear neutrophiles is manifest even in those septic conditions in which there is no actual increase of the total number of the leucocytes.

The increase of the polynuclear neutrophiles, however, is at times but little above the maximum normal, so that doubts can still arise whether or not a septic condition exists. An advance beyond this point has thus far not been made. This is peculiar in view of the fact that every laboratory worker must surely have noted the constancy with which the eosinophiles are diminished or absent in all septic conditions, using the term in the widest sense of its meaning. The text-books on hematology are silent on the significance of this fact; the diminution of the eosinophiles is noted, but is not commented upon. In the past the *increase* of the eosinophiles in various pathological conditions has received the attention of the laboratory worker but not their decrease. For the future we should urge the recognition of the undoubted fact that in all septic conditions whether associated with an increase of the total number of the leucocytes beyond the normal, or not, there goes hand in hand with a more or less marked relative increase of the polynuclear neutrophiles a distinct relative decrease of the eosinophiles, if indeed they are not absent altogether. So far as infection with the common pus organisms is concerned, viz., the various staphylococci, and streptococci, as also with the pneumococcus, the typhoid bacillus and the diphtheria bacillus, this rule is without exception. We should urge upon the surgeons the recognition of this fact and can then hope that in the future normal appendices are removed less frequently than is now unfortunately the case. On the other hand, we should emphasize the necessity of the differential leucocyte count by the general practitioner in all obscure cases of abdominal pain.

SOME FACTS ABOUT COLLEGE ATHLETICS.

IF one were in quest of a refutation of the oft repeated fallacy that college athletics were injurious to the participants; that such strenuous efforts on the part of the flower of our youth tended to diminish their intellectual vigor and brutalized them; that the great expenditure of nervous force and energy exhausted these young athletes and rendered them unfit for their life-work; or that they prematurely die of heart disease or consumption, one has simply to go over a recent article by Dr. George L. Meylan, new director of the Columbia Gymnasium, contributed to the *Harvard Graduates' Magazine* on Harvard University oarsmen.

In dire prognostications relative to these evils and the fostering effects of college athletics too often has the solitary swallow been made to bear the whole burden of a summer's rhapsody. The isolated examples of early death have been quoted as "I told you so's" by many physicians who have never had presented for their consideration any series of observations of sufficient breadth to warrant any conclusions. We as physicians should be the last to countenance college athletics if it can be shown that they uniformly work injuriously, but apart from the well-known tendency in some directions, to develop excessively along isolated lines, the medical point of view has coincided with the conclusions reached in Dr. Meylan's studies.

Having been led to an investigation of the subject by the asservation of a former Harvard oarsman that all the men who had been in his boat had died young, Dr. Meylan went over the records and found that the former oarsman suffered very severely from a bad memory and that instead of premature deaths among Harvard oarsmen excellent longevity and an increased expectation of life was the rule. Rowing has al-

ways been considered one of the best of the forms of athletic exercises, and in passing we would like to suggest to Dr. Meylan that he make a similar study for track athletics, a form of exercise, especially in the short runs, that is viewed with suspicion by even the broadest of your cult.

As to results: From 1852 to 1892, 152 different men were on record as having rowed on the Harvard Varsity crew, 123 were living, nearly all of whom were personally seen by Dr. Meylan. Thirty-two races had been rowed, with crews of 4, 6 and 8. The average age of these rowers was twenty years. In order to arrive at some standard of comparison the expectation of life tables of our large insurance companies were consulted and these showed that the total number of years of life of these oarsmen was 346.08 as compared with 337.6 the number that they might be expected to live.

Dr. Meylan then presents an extensive table including all the oarsmen and comes to the conclusion that Harvard oarsmen do not die prematurely and that they live longer than healthy men accepted by life insurance companies.

Referring to the causes of death in 32 oarsmen he finds that 6 were killed in the Civil War, one was run over by a railroad engine, and another met his death in a carriage accident, 2 died of heart disease, 3 of pneumonia, 2 of apoplexy, 2 of paresis, 1 of cancer, 1 of phthisis, 2 of Bright's, 1 of alcoholism and 1 of tropical climate. In ten the cause of death could not be ascertained with definiteness, but direct relationship of athletics to the death could not be traced.

It is interesting that of the survivors not one has made a failure in life. Five only occupy subordinate positions, the names of the rest are to be found among the most noteworthy of this country's citizens. At least ten per cent., who have been out of college fifteen years, are to be found among the list of eminent men. Certainly a sufficient refutation on the "brutalizing" tendencies of college athletics.

We would welcome other studies of selected groups that our notions concerning college athletics might be furbished and put in order, as this paper of Dr. Meylan's has contributed to do for rowing at our oldest American university.

Eastern Medical Library Opening.—The Eastern Medical Society of the City of New York opened its library and club-rooms in Clinton Hall, 151 Clinton street, last Tuesday evening. Addresses were delivered by Dr. Abraham Jacobi, ex-Justice Julius M. Mayer, Dr. Kenneth W. Millican, and Dr. Joseph D. Bryant.

ECHOES AND NEWS.

NEW YORK.

Medical Association of Greater New York.—The next regular monthly meeting will take place Monday, March 14, at the Academy. The following program has been announced: (1) Observations on Dilatation of the Stomach and on Gastroptosis, by Robert Coleman Kemp, M.D.; (2) The Consultant's Point of View, by William H. Thomson, M.D.; (3) Gastro-diaphany (Trans-illumination of the Stomach), by Max Einhorn, M.D.; (4) Dilatation of the Stomach, by George R. Lockwood, M.D.; (5) Gastroptosis, by Achilles Rose, M.D.; (6) The Surgeon's Point of View, by Robert H. M. Dawbarn, M.D., and George E. Brewer, M.D.; (7) Relation of X-ray and Radio-active Solutions to Examination of the Stomach, by Sinclair Tousey.

Site for Bellevue Training School.—The Bellevue Training School for Nurses has bought, for about $50,000, the property, 423 to 431 East Twenty-fifth street, a plot 125 by 100, and will erect thereon a six or seven story building to be used as a training school and nurses' home. The school heretofore has been quartered in some three and four-story buildings on Twenty-sixth street immediately at the rear of the site just purchased. These old structures will be used in connection with the new building, and it is said that the latter may eventually be extended over the entire property.

New York Academy of Medicine.—The Section on Medicine will meet next Tuesday evening, March 15, at Nos. 17-21 West Forty-third street. The following is the program: (1) Presentation of Cases and Specimens: Trichinosis, by Wm. B. Noyes, M.D.; (2) Clinical Reports: Two Cases of Cerebrospinal Meningitis Cured by Intraspinal Injection of Lysol, by Morris Manges, M.D.; (3) Papers: (*a*) Feeding in Tuberculosis, by John B. Huber, M.D.; (*b*) On the Sanitary Surveillance of Tuberculosis in New York City; illustrated by exhibits prepared for the St. Louis Exposition, by Hermann M. Biggs, M.D.; (4) Discussion of papers.

Columbia University Notes.—The trustees of Columbia University, at their last regular meeting, approved the proposal to incorporate the College of Pharmacy on terms similar to those by which Barnard and Teachers' colleges became a part of Columbia some years ago. President Butler becomes president of the college, the dean of the College of Pharmacy will sit in the Columbia University council, and the educational management of the College of Pharmacy will be subject to the general direction of the University Council, the College of Pharmacy retaining much of its autonomy. Edwin B. Cragin, M.D., professor of obstetrics, was appointed professor of gynecology; Harry McMahon Painter, M.D., attending physician in the New York Lying-in Hospital, was appointed to the newly created professorship of clinical obstetrics; Gorham Bacon, M.D., now professor of otology in the Cornell University Medical School was made clinical professor of otology, vice Albert H. Buck resigned, and William K. Simpson, M.D., was made clinical professor of laryngology in place of Prof. Lefferts.

New St. Francis Hospital.—The Sisters of the Poor of St. Francis, who for thirty-eight years have conducted St. Francis' Hospital, in East Fifth street, are erecting a new hospital on the block bounded by One Hundred and Forty-second street, Brook avenue, One Hundred and Forty-third street, and St. Ann's avenue, directly opposite St. Joseph's Hos-

pital for Consumptives. There will be 19 large wards, giving space for 304 beds, and 40 small wards, a number of which will be used for private patients. In addition, there will be constructed a house for the sisters, 120 by 54 feet, the lower floors of which will contain the kitchens and store-rooms and a handsome chapel, 48 by 80 feet. There will also be a garden for the patients.

Immigration and Disease.—In a recent number of the *Popular Science Monthly*, Dr. Allan McLaughlin, of the U. S. Marine Hospital Service, discusses very forcefully the dangers to which Americans are subjected by the present lax methods of preventing diseased foreigners from taking up their abode among us. It has come to be pretty well known from the constant harping of certain newspapers and magazines that this country is being rapidly supplied with adventurers from foreign lands; but comparatively few citizens have anything to say about it save that we are a wonderful people and rightfully stand forth as the inhabitants of "the land of the free and the home of the brave." That fact satisfies their patriotism, and occasionally a man's patriotism obscures almost all of his other good traits. But the most potent reason against even promiscuous hospitality is the introduction of loathsome and dangerous diseases, such as trachoma and favus among a hitherto immune population. According to Dr. McLaughlin there has been a great deterioration in general physique among the foreigners who have come here since 1880. Previous to that time most of the immigrants hailed from the northern or western parts of Europe and belonged to the stocky, healthy Celtic or Scandinavian types. To-day the bulk come from the South and East and are in comparatively poor physical condition. The weakest are the Hebrews, of which about 70 in every 100 remain in or near New York. Then come the next in order, the Italians, who are so commonly found in our charity hospitals and asylums. Then the Slavs, the Irish and finally the Swedes and Norwegians, of whom only 18 per cent. take up their permanent residence in this city. As a prophylactic against the spread of infectious diseases by this method our Government has instituted an inspection of both steerage and cabin passengers, sending back all those physically unfit to land and fining the steamship companies $100 for each offense in allowing these objectionable ones to take passage. But, of course, there is Canada, and it is taking the best wit at our command to keep the border line from becoming the actual portal of entry for those sent back from New York. It would seem that not only the actual presence of disease, but a physique likely to soon give way under the stress of our climate should be equivalent to deportation. Or each applicant might be required to show a certain standard physique if between the ages of eighteen and forty-five years. Whatever is done ought to be put under way as soon as possible, for it is alarming how such diseases as trachoma and favus—both foreign to American soil—are spreading, especially among school children. In closing his article Dr. McLaughlin says, "If the thousands of recruits for the sweat-shop army could be checked for ten years the existing tenement-house problem would solve itself. The terrible congestion of the tenements would be relieved, the scale of wages for the sweat-shop worker would be elevated, and the general sanitary conditions of life on the lower East Side could be improved sufficiently to reduce the menace to public health from this cause to a minimum." This seems like a broad and sweeping generalization, but it is made by a man who knows what he is talking about.

New Mt. Sinai Hospital.—On March 15 the new Mount Sinai Hospital, at Fifth and Madison avenues and One Hundredth and One Hundred and First streets, will be opened to the public for inspection. Two days will be given over to the reception of visitors, namely, March 15 and 16. Aside from its liberal allowance of sunshine and air, unusual for such an institution in a large city, the hospital's size, considered in the light of the number of patients who can be treated within the walls of the various buildings, is perhaps its most striking and interesting feature. No fewer than 450 patients can be housed in the various wards at one time, which is more than any other hospital erected by private donations will hold. In addition there will be accommodations for 52 private patients. Scarcely less interesting are the opportunities provided to enable convalescents to recover their strength while still under the advice and treatment of the physicians of the hospital. In view of a lack of surrounding grounds a roof garden has been arranged for them, in which they can bask in the sunshine, and from which to the west they will obtain a splendid view of Central Park. Furthermore, adjoining the ward in which they are undergoing treatment will be a room where they can enjoy themselves in quiet games to the extent their returning vitality will allow. Although the new institution will be opened for inspection on the two dates mentioned, patients will not be admitted until the morning of March 21. Neither patients nor furniture will be moved from the old hospital to the new. Admissions to the old structure were stopped on Thursday last, but those who are being treated there will be allowed to remain until they have been nursed back to health. The entire group of new hospital buildings will have cost, when completed, $2,250,000. They will include the Administration Building, to which will be joined two buildings containing the medical wards, creating a structure which is really three in one. Then the group will comprise the Dispensary Building donated by the family of Meyer Lehman, the Nurses' Building, with accommodations for 160 nurses of the working corps; the Pathological Building, donated by Adolph Lewisohn; the Isolation Building, the Laundry and Kitchen Building, the Children's Pavilion, donated by Henry L. Einstein; the Private Pavilion, donated by the Guggenheim family, and one or two minor buildings. Of all the various interior innovations the Hydro-Therapeutic Pavilion is perhaps the most palatial. It is almost a complete house of marble, providing the opportunity for all sorts of baths prescribed by up-to-date physicians with the appurtenances therefor. The superintendence of the hospital will devolve upon Dr. S. S. Goldwater, who has made the superintendence of hospitals a special study. He was graduated from Bellevue Medical School in 1891. The corps of visiting physicians in the various departments will comprise: Consulting Physicians—Dr. E. J. Janeway and Dr. Abraham Jacobi; Consulting Surgeons—Dr. W. F. Fluhrer and Dr. D. M. Stimson; Attending Surgeons—Dr. A. G. Gerster and Dr. Howard Lilienthal; Adjunct Attending Surgeons—Dr. Charles A. Elsberg, Dr. A. A. Berg, Dr. Joseph Wiener and Dr. A. V. Moschcowitz; Attending Physicians—Dr. N. E. Brill, Dr. M. Manges, Dr. Alfred Meyers, Dr. J. Rudisch and Dr. H. Koplik (children); Adjunct Attending Physicians—Dr. H. W. Berg, Dr. D. H. Davison, Dr. E. Libman and Dr. Albert Kohn; Attending Eye Surgeon—Dr. E.

Gruening; Adjunct Attending Eye Surgeons—Dr. Carl Koller and Dr. Charles H. May; Attending Gynecologists—Dr. Joseph Brettauer and Dr. Florian King; Adjunct Attending Gynecologists—Dr. H. N. Vineberg and Dr. S. M. Brickner; Attending Neurologist—Dr. B. Sachs; Adjunct of the Neurologists' Department—Dr. W. H. Hirsch; Attending Dermatologist—Dr. L. Lustgarten; Adjunct Dermatologist—Dr. F. Leviseur; Radiographist—Dr. Walter M. Brickner; Assistant Radiographist—Dr. E. H. Eising; Attending Laryngologist—Dr. D. B. Delavan; Adjunct Attending Laryngologist—Dr. Emil Mayer.

PHILADELPHIA.

Operation by Dr. Ridlon.—A demonstration of the Lorenz method was given in the Jefferson Hospital March 1 by Dr. John Ridlon, of Chicago. The patient was a child of two years and the dislocation was reduced perfectly. At the same clinic were exhibited several patients operated upon last year by Dr. Lorenz and Dr. H. Augustus Wilson. Perfect cures seemed to have been attained in at least two of the cases.

Civic Club to Aid Fight Against Tuberculosis.—The Civic Club of Philadelphia gave up nearly all of its regular meeting March 5 to a consideration of methods for combating tuberculosis. The meeting was held in the College of Physicians and was addressed by Dr. Lawrence F. Flick, of the Phipps Institute. The Club proposes to aid in the movement against tuberculosis and other public organizations are expected to join. Efforts will be made to secure legislation to enforce preventive and curative measures and the erection of special hospitals.

New Sewer System to Prevent Typhoid.—The continued prevalence of typhoid fever, 195 cases having occurred during the past week, has caused the city authorities to consider plans for disposing of the sewage by means of the septic tank system. The plans contemplate the construction of large intercepting sewers along the Schuylkill and Delaware rivers, converging at a point near where the rivers meet. Here the plant for disposing of the sewage will be erected. If this project be carried out it will place Philadelphia in a position to legally attack the cities above its site for polluting the rivers.

Suture of the Heart.—A colored man, thirty years of age, was operated upon for a stab wound of the heart, at the Jefferson Hospital February 29, by Dr. Francis T. Stewart. The man walked some distance to the hospital after receiving the wound and was operated upon forty-five minutes after the injury was inflicted. The wound was found to be near the base of the left ventricle, the external opening being about one inch in length. This was closed by means of six sutures. The patient has since done fairly well with the exception of having a rapid pulse.

Biography of Dr. William Pepper.—The *New York Times Saturday Review of Books* for March 5 contains a very appreciative and highly commendatory review of Francis Newton Thorpe's life of William Pepper, M.D., LL.D., Provost of the University of Pennsylvania. The book is published by the Lippincotts of Philadelphia.

CHICAGO.

Gift to Augustana Hospital.—According to the will of the late Thomas G. Lowther, a sum of not less than $20,000 from the residue of the estate will be given to this hospital.

Chicago Medical Society.—At a meeting held March 2, 1904, there was a symposium on Syphilis. Dr. Hugh T. Patrick presented a woman, forty-one years of age, whose trouble dated back to 1899. He saw her in 1901 for the first time. She suffered from dizziness, failure of vision, intense headaches, considerable mental and physical hebetude. Following this she developed double vision, which lasted for a few months. Acuity of vision diminished rapidly, according to the statement of the patient. After having had this trouble for some time, she sustained a fall and was unconscious for a short time. When she regained consciousness she vomited. A month later she had another fall, and was also unconscious for a short time. During this time the severe headaches continued. After several months of these headaches, mental hebetude, double vision, and two unconscious attacks, she was removed to St. Luke's Hospital, and on the day following her arrival became unconscious, and remained so for twenty-four hours. She vomited just before she became unconscious. When she regained consciousness, everything looked blurred, and the left side was paralyzed. The arm became weak first, then the leg, and later the face became involved. With the left hemiplegia there was marked sensory disturbance; marked anesthesia, which continued for a considerable time. Two years after the attack, when patient had regained very good use of the left side, there was still considerable subjective trouble on that side, but very little objective. Patient uses the left hand for practical purposes, but it is not as dexterous as it was, and feels queer. She has complete homonymous hemianopia. The visual field is normal on one side, but gone on the other. As the result of her trouble, patient has permanent hemianopia, although she has nearly recovered from her left hemiplegia. Patient is absolutely ignorant of any specific infection. Dr. Patrick presented another case, a woman, twenty-one years of age, whose mother is at present suffering from tabes, with optic atrophy. The oldest child, a son, died about two years ago from general paresis. The next child, also a son, is at present suffering from tabes, with optic atrophy. Patient is the third and only remaining child, who, as an infant, had snuffles, and later developed mucous excrescences. Two and a half years ago she had a typical interstitial keratitis, but up to three years ago, aside from the trivial ailments of childhood, she was well. One day, while sitting on the step, she had a sort of stroke without loss of consciousness; became weak on one side, more especially in the face. The next morning she had another stroke which involved all of the right side. This attack was transient. A month later she had another attack of right hemiparesis which was a little more severe, and three months later a fourth attack, which was very severe, which left her completely hemiplegic on the right side with aphasia. First the face, then the arm and leg became involved. A year and a half ago, patient developed typical Jacksonian fits. These fits started with twitching and drawing in of the right side of the face, which extended to the arm, then to the leg, after which she had a general epileptic attack. Sometimes the spasm does not go so far. The face and arm may be convulsed, without loss of consciousness. Sometimes she has a severe attack which terminates in a general convulsion. Attention was called to the defective teeth of the patient. She also has a disseminated choroiditis. Patient showed unmistakable signs of hereditary syphilis, and Dr. Patrick said the question arose whether the two boys inherited syphilis or had it communicated to them as children. Either case was possible;

but the family showed the relation between specific disease, tabes and general paresis.

Dr. L. Blake Baldwin showed a Chinaman with syphilis. He had treated eleven cases of this disease in Chinamen. He brought the case for diagnosis. As it was difficult to get a history of such cases, he ventured to say that ninety per cent. of the cases of Chinamen who consulted physicians had this disease. With this thought in mind he has given all of them iodide of potassium with good results in most cases. When these patients presented themselves with facial paralysis, paralysis of the arm and leg, with large ulcerations on the leg, it was wise to give them iodide of potassium. The patient denied any initial lesion. Dr. Baldwin showed another case, a man, with a diagnosis of syphilis. Patient had a chancre eighteen years ago. He now had syphilitic iritis, but had improved considerably under the use of iodo-nucleoids. He mentioned a case similar to this that had made a perfect recovery. About five years ago this patient had a paralytic stroke on the left side, so that he was unable to move his fingers, but the paralysis lasted only half an hour. He also showed some cases of syphilitic lesions of the mouth. One patient had a chancre fourteen years ago, but no eruption on the body. Since that time patient had had two soft chancres about a year ago, which were cauterized by a physician.

Dr. Frederick Menge showed a boy, twelve years of age, who had hereditary syphilis. Patient had an active proliferating gumma in the nose, springing from the septum on both sides, filling the interior meatus and occluding both nostrils. He had also complete erosion of the uvula.

Dr. George F. Suker showed a boy who had a typical syphilitic head. He had the tripod of Hutchinson; interstitial keratitis, otitis media, and saddle nose. Patient also had syphilitic rhinitis; bilateral dacryocystitis; stenosis of the lacrimal duct. Patellar tendon reflex was not lost. Patient had what is called the Darier tooth; atrophy of the upper jaw and of the hard palate. Patient had had these affections since the second week of birth. Attention was called to the typical Hutchinson's teeth. The boy was a typical example of inherited syphilis.

Dr. E. A. Fischkin presented a patient who gave a history of having had a primary lesion some twelve years ago, the nature of which was not definitely known. Patient said he did not have secondary lesions, but did have mucous patches, and was free from other manifestations of syphilis for twelve years. Patient had been married five years, and had healthy children. About fourteen months ago purpuric spots began to appear on the lower extremities. Three months ago tubercles appeared on the side of the nose, which were circinate in form, gradually enlarged, and finally ulcerated. Patient was put on iodides and given inunction treatment. Soon the whole leg was covered with purpura, but the spots were closer together, particularly on the surface where the ointment was rubbed in. The question arose in the author's mind as to whether he was justified in calling the case purpuric syphilis, or was the purpura due to the toxic effect of the treatment. Against the latter, it should be said that the patient had purpura twelve weeks ago without treatment. The second case was a girl, fifteen years of age, who presented a typical tertiary, ulcerating syphilide on the leg. Patient also presented syphilitic scars of the type represented by atrophy and pigmentation. The history was entirely negative. The disease was of two years' duration. If she had acquired syphilis, the primary infection must have occurred when she was twelve or thirteen. There were a number of scars on the leg and a general adenopathy.

Dr. George F. Suker showed two cases of syphilitic iritis. In one the eye was very painful, while in the other there was no pain. One had a small corneal ulcer. This patient admitted having had syphilitic infection about a year ago, but now had the secondary manifestations of the disease, with marked adhesions of the iris, and excessive proliferation of the pigmentary layer of the posterior surface of the iris, with a large portion of the anterior surface of the capsule of the lense being involved. There was great reduction of sight, with pupillary adhesion. The corneal ulcer was situated toward the nasal side.

GENERAL.

Loss to Johns Hopkins Hospital.—By reason of the Baltimore fire the hospital has lost about $60,000 of annual income. This diminution of income must last at least two years, and possibly longer. This loss of income represents about a million and a quarter's worth of property which belonged to the hospital and was improved with warehouses and office buildings. The real estate of the hospital was scattered over a large territory, and the insurance of the property was not for total loss, but for the contingencies of ordinary fire. By reason of the fire 64 out of 80 warehouses were burned, and the actual loss of property beyond insurance is probably between three and four hundred thousand dollars. The loss of income, however, is much greater and much more permanent, because, in the great rebuilding it will probably not be wise to rebuild all the warehouses, and much real estate must necessarily lie idle. Under the circumstances the hospital authorities look forward to a considerable deficit for the next two years, unless some means can be devised for temporarily patching up the income.

Winter Weather and Public Health.—The *Times* speaks editorially of the severity of the weather during the past three months and of its influence on the general health as follows: "The most natural question to arise in the discussion of the severity of the past winter is its influence upon the public health. Outside of forms of disease attributed to the bacillus of influenza there is nothing in the current mortality statistics to attract especial attention. In other respects the public health is normal. Including these, the situation is extremely disquieting. The number of deaths occurring in New York city last week was greater than for any week of the winter season since the great grip epidemic of 1892-3. The number was 1,797, against 1,682 for the week preceding. Bronchitis and lobar pneumonia predominate among the causes certified by physicians in their reports of deaths, and the relatively small number of deaths assigned to influenza is explained by the fact that more exact diagnosis than was formerly possible permits of a more scientific classification. However, it is the grip microbe which is doing the work. Only a few years ago this specific bacillus was isolated and recognized, and in examinations of the sputa of patients in the hospitals suffering from diseases of the respiratory organs it is found in from 70 to 90 cases in the hundred. The infectious area is by no means strictly local. It exists actively in most of the nearby towns north, east, and south of New York, and in New Jersey is reported to have taken a somewhat distinctive type with the compli-

cation of swellings of the submaxillary glands. Public sanitation, with our present knowledge, can do but little to correct these conditions. The only effective safeguards will be found in prudence, and in the observance of avoidance of contact infection."

To Rid Mexico of Yellow Jack.—Dr. Owens, one of the Southern health officers who visited Mexico for the purpose of inducing that country to cooperate with the United States in getting rid of yellow fever on the frontier, declares that the Supreme Board of Health of Mexico will do all in its power, and is well provided with funds for that purpose. The most important sanitary work undertaken is that at Vera Cruz, which is regarded as the centre of yellow fever infection in Mexico. The Mexican board has at its disposal $7,000,000 for the work of rehabilitating Vera Cruz, which will be devoted to sewerage and drainage work. The town is divided into four districts, with a medical officer in charge of each. Each one of these medical officers has under him a large corps of sanitary inspectors. A thorough tour of inspection is made of all suspected or infected districts each day, and each evening a report is made of the number of cases in each district. Oil is being used freely. Marshes surround Vera Cruz, and every possible precaution is taken to diminish the number of mosquitoes coming from them.

Impure Water for Cities.—"Authoritative information from Cleveland," says the *Times*, which paper takes an advanced position in matters sanitary, "shows that city to be fighting a typhoid epidemic, already serious and daily gaining headway. It had attained the importance of 68 cases in one day on the first of the present month, and the official returns for February show 465 cases reported and 45 deaths. The water of Lake Erie is polluted. The Philadelphia *Ledger* reports Health Officer Abbott as announcing that in that city a sweeping typhoid epidemic is threatened, having reached the stage of 30 cases a day. In 1903 there were 8,000 cases of typhoid reported in the city. The Schuylkill is polluted. In probably twenty cities and towns the conditions which menace Cleveland and Philadelphia are now being dealt with in the crude way customary when the limited machinery of the local sanitary administration is taxed to the breaking point. Why is it that experience teaches communities so little in matters so intimately affecting the public health as drainage and water supply? The *Public Ledger* says of the conditions tributary to the present situation in Philadelphia: 'At the Shawmont pumping station great difficulty is being experienced in getting water, owing to the serious break at Flat Rock Dam. Centrifugal emergency pumps have been installed on the towpath, and dirty, slimy water is being pumped directly into the pool. On last Tuesday the water above the dam was 17 inches below the breast. Owing to the rain, the water rose 5 inches in the afternoon. As long as this break is unclosed, there will be little opportunity for the water to settle before being pumped from the river.' No doubt the average citizen reading this will shrug his shoulders and think how regrettable it is that such an accident should happen with consequences so serious. That he will do more than this is scarcely to be expected. One would suppose that the effect of such an announcement would be comparable to that of ringing a general fire alarm; but it is not, never was, and perhaps never will be. To create and sustain an intelligent public interest in matters affecting the public health is one of the most difficult of human undertakings."

An ex-Prisoner on Professional Criminals.—We quote with approbation the following from the *Nineteenth Century:* "During the period of my incarceration I conversed with some hundreds of prisoners belonging to what is known as the professional or habitual criminal class, those desperate, hardened, clever criminals of whom we hear and read so much. I got at these men's sentiments, ideas and feelings, and I believe I am safe in saying that in only two instances did I encounter prisoners whom I put down as utterly irreclaimable. As for the remainder, they were professional criminals simply because no other profession was open to them. To suggest, as some writers do, that these men are burglars, housebreakers, pickpockets or whatever it be, because they hanker after pursuing these occupations, is to my mind sheer nonsense. These men are professional criminals for very much the same reason as ninety-nine hundredths of the women who nightly patrol the streets of the metropolis are professional prostitutes—because their wills have been weak and circumstances have been too strong for them. To assert that these professional criminals are mere wild beasts, impossible of being brought back to the path of rectitude, is, to my thinking, not only absurd, but untrue. No one attempts the reclamation process either in jail or out of it. Once a man has worn a prison suit, the world, whatever may be its protestations to the contrary, tacitly declares him an outlaw, every man's hand is against him, he is a pariah, an outcast; and, unless he be a man of strong will and fierce determination, or has private means or friends to assist him, he almost naturally relapses into crime. It is, in fact, his only alternative, and the men he has met in prison are the only persons who will assist him. I confess I feel sick when I read the puling sentimentality which from time to time appears in reviews and newspapers anent the innate depravity of the criminal, knowing as I do the struggle, the almost hopeless struggle, the ex-prisoner has to make if he is to exist without infringing the law. No doubt there are prisoners' aid societies which receive and spend the vicarious charity of the public. These societies will, I know, receive the prisoner on his discharge and make him clearly understand that he is an ex-prisoner; they will dole him out the paltry gratuity he has earned in prison, and, if he wants anything else, they will employ him to chop wood or at some such congenial labor—at a profit to the society. These institutions may do excellent work for all I know, but the excellent work has not come under my notice. How they expend their funds has always been a mystery to me, because in not one solitary instance—and I have made hundreds of inquiries—have I been able to trace the fact of their having rendered efficient aid to any discharged prisoner."

In view of this criticism we would call attention to the following item concerning the report of the New York Prison Association Report.

Faulty Prison Systems.—The Prison Association of New York has just submitted to the legislature its fifty-ninth annual report. It is confined almost entirely to subjects which can only be remedied by legislative action. The whole report, which is signed by Charlton T. Lewis, chairman, and S. J. Barrows, corresponding secretary, is an elaborate argument in favor of the reorganization and unification of the prison system of the State. The necessity of considering the problem of crime as a whole is made evident, and State control is recommended for all persons convicted of violating the State laws. The enforced idleness of prisoners in county jails is deplored, as well as the system in some counties of paying sheriffs so much a day for each prisoner they keep. Remedies for the various abuses are suggested, and they can be effected, it is said, "with

comparative ease and with small expense." The report opens by saying that "every year makes it more and more evident that crime in this State can only be adequately treated by considering the problem as a whole," and continues as follows: "The criminal is actually in advance of the State in taking advantage of the changed conditions of modern life. While the State continues to treat crime as if it were a local matter, the criminal is anything but local in habitation or in his depredations. He skilfully avails himself of modern methods of transportation to change his habitation and his field of operations from place to place, in search of profit or safety. He has discovered that with uniform laws and uniform judicial procedure in the State, there is no uniform prison administration. In fact, there are in New York sixty-two prison systems—namely, one for the State and one for each of its sixty-one counties. The tramp or the vagrant chooses for a winter residence the county, where he can get the most comfort with the least work, turning the weakness of the system to his own advantage. In many other ways local control and divided responsibility defeat efficient discipline and uniform and economical administration. We beg leave to call your attention to some of the anomalies which point to the necessity of a reorganization and unification of our prison system.

"One of the most obvious lies in prison administration. Neither the State commissioner of prisons nor any other State authority exercises any control over discipline, treatment, feeding, education, or labor in county jails or county penitentiaries. This association visits and inspects them as does the State commission of prisons, but like that commission has no powers of control. The inspectors can do nothing to improve the conduct of local institutions or to remedy abuses, save by personal appeals to the sheriff, or to county parliament, the Board of Supervisors, to which he is responsible. There is, therefore, no uniformity in the condition or treatment of prisoners in the sixty-one counties except that uniform idleness prevails in the jails throughout the State.

"The present system—if a method so irregular can be called a system—is incongruous. The Penal Code is the same in all parts of the State, but there are glaring inequalities in the application of the penalty. The equality of duration in a punishment is one thing; but equality of condition quite another. A sentence of two years to such a prison as Sing Sing, especially with two men in a cell, is a far heavier penalty than the same term in a healthy modern prison. The county jails vary so much in condition that a month in one is worse than three months in another, so that the penalties imposed do not represent any uniformity in punishment or discipline. The county jails are notoriously unfit for the discipline and correction of convicted prisoners. Experience has shown that uniformity of standard and condition cannot be attained even under a uniform law for the counties when the law does not efficiently provide for its enforcement. There is hardly a sheriff or supervisor in the State who is not guilty of violating laws as conspicuously as are the prisoners under his charge. It is extremely difficult, indeed, for such officers to comply with some of the laws under local imitations. It is important to note that a large part of this difficulty has been created for the counties by the State itself. This is especially true in regard to prison labor.

"Before the passage of the Constitutional Amendment, which provides that prison-made goods shall not be sold in the open market, but only to the State or to political divisions thereof, four counties in the State maintained penitentiaries in which every prisoner except those physically disabled, had the mental, moral, and physical advantage of a full day's work, and these institutions were more than self-sustaining. The passage of the Constitutional Amendment destroyed the industries of these county penitentiaries. That the taxpayers of the counties are compelled to support in idleness several thousand able-bodied prisoners is a frightful anomaly of our Government; yet even this is of slight moment compared with the moral and physical evils which arise from keeping prisoners in enforced idleness. It is ten years since the Constitutional prohibition was adopted and seven years since it went into effect (January 1, 1899). If any one wishes to know the result of this prohibition in keeping men from productive labor, let him go to the Rochester penitentiary and see a hundred men in one room and a hundred in another sitting in absolute idleness under the oversight of keepers waiting for the time to pass. The monotony of this punishment is relieved occasionally by marching the men around the yard. Here is an inert mass of humanity forcibly removed from society and maintained like a stagnant pool in a corrupting miasm of inactivity as if the only object of such an institution were to breed the scum of civilization, and to propagate it in the community. For it must not be forgotten that the most of these men in the course of six or nine months are going out of prison worse than when they came in. If individual idleness is bad, collective idleness is much worse. To see it in its most evil and contaminating aspect, we must go to the county jails throughout the State, where the orderly silence which prevails at the penitentiary gives place to the freest and most contaminating association in the corridors.

"It may be said that notwithstanding the constitutional limitation of labor, the law of 1896 requires that prisoners in county jails shall be employed six days in every week, and that it is the duty of sheriffs and supervisors to enforce the law. This is true, and in several counties these officers are neglecting even the meager resources which the Constitutional Amendment left in their hands. But the main difficulty is that while the Constitutional Amendment destroyed the market, the subsequent law requiring labor did not restore it. If supervisors and sheriffs in the different counties are asked why they do not keep prisoners at work, they always have to answer: (1) There is no place in the jail where men can work. (2) There is no way of disposing of the product if prisoners did work. Both of these answers have great force. Our jails have no workshops where machinery could be installed, and in most of them the cells are too small and too dark to permit of even hand labor. In most of the counties the county institutions afford no sufficient market for the product of prison industries to encourage the introduction of them."

The fee system as applied to sheriffs in criminal cases is commented on as follows: "It is a blot on the good name of the community that a discredited system which has been discarded by nearly every civilized nation should be maintained here as a source of revenue for local politicians. It is not the county alone; it is the State which pays the cost. The fee system instead of diminishing crime tends to increase it; it substitutes detention for prevention and reformation."

Lunacy in Great Britain.—The fifty-seventh report of the British Commissioners in Lunacy reveals a most serious situation; according to their tables there were in England and Wales on January 1, 1903, 113,964 notified lunatics, 3,251 in excess of the number on the corresponding day in 1902. This increase for 1902 contrasts with one of 2,769 for 1901, and 1,333 for 1900. The average annual increase in

the number of lunatics for the five years ending December 31, 1902, was 2,398. Thus the increase in the year 1902 exceeded the annual average increase in the preceding five years by 853. The latest returns show an increase in the county and borough asylums of 3,749 patients over the number for January 1, 1902. The pauper patients (47,102 males and 56,692 females) have increased in the county and borough asylums by 3,628. As regards the ratio of the insane to the population the Commissioners point out that the aggregate of lunatics under official cognizance on January 1, 1903, gives a ratio of one to every 293 persons of the general population of England and Wales. In 1879 the ratio of lunatics to the general population was 1 to 363, in 1889 it was 1 to 337, and in 1899 it was 1 to 303. The proportion has continued to increase steadily ever since, and it now amounts to 1 in 293. It appears that the rate of recovery is higher among women than among men, but more women die than men. Alcoholic intemperance is assigned as the cause of insanity in 23 per cent. of the males, and nearly 10 per cent. of the women. The male epileptics are more numerous than the female by 30 per cent.

Extermination of Mosquitoes.—"At a luncheon in Liverpool, the other day," writes the *Evening Post*, "Prof. Royce, recently returned from Egypt, gave an interesting account of the success which has attended the efforts to extirpate the mosquitoes and malaria from Ismailia. He said that when Major Ross visited Ismailia in September, 1902, there were 2,000 cases of malaria annually in a population of 9,000 people, of whom 2,000 were Europeans. The authorities at Ismailia loyally carried out his suggestions as to filling up marsh land close to the town and cleaning out small irrigating channels and stagnant waters. That involved an expense of $22,000, and at the same time they organized a drains brigade and a petroleum brigade, and now people could sleep in any of the houses in the European quarter without mosquito nets. Malaria cases had been reduced from 2,000 a year to 200. As a matter of fact, there were no fresh cases of malarial infection in Ismailia; there had been no deaths among Europeans during 1903, and only four among natives, against 30 deaths the year before. The improvement was so wonderful that Prince d'Arenberg, president of the Suez Canal Company, hopes soon to see Ismailia the sanatorium and watering place for Cairo. Major Ross, who was present, remarked that the success of the anti-malarial campaign at Ismailia had taught two things—that it was possible to rid a large town entirely of mosquitoes, and that it was equally possible to eradicate malaria. He had been asked to draw up a report as to malaria cases in India, which were responsible for 300,000 admissions to hospitals from the troops and jail prisoners. With the Ismailia figures before him he felt confident that these high figures would be reduced soon by at least one-third."

OBITUARY.

Dr. William Rankin, Jr., for over thirty years a practising physician of Newark, N. J., died Feb. 27, aged fifty-six years. He was a graduate of Rutgers College and the College of Physicians and Surgeons in this city, and also studied in the hospitals at Vienna, Austria. He was for years on the visiting staff of the Newark Charitable Eye and Ear Infirmary, and Secretary of the old Newark Library Association, and a member of the American Opthalmological Association, the American Otological Association, the New Jersey State Medical Society, and the Essex District Medical Society.

Dr. Theodore Y. Kinne, of Paterson, N. J., died at his home last week of heart trouble. Dr. Kinne, born Aug. 27, 1838, near Syracuse, N. Y., was a descendant of the early settlers in this country from England. After a year's attendance at West Point as a cadet, he resigned and took up the study of medicine. He was valedictorian of his class in the Albany Medical College in 1862. In 1864 he went into the Union Army as an assistant surgeon of the One Hundred and Eighty-fourth New York Volunteers, and later on he was transferred to the regular service of the army. He came to Paterson in 1867.

Dr. Moses D. Knight died at his home in Clinton, N. J., last week. Overwork resulted in an attack of heart disease, which terminated in his death. He was a graduate of the University of Pennsylvania and seventy years old.

Dr. Ogden Curtis Ludlow, whose death was noticed in last week's Medical News, died of typhoid fever. Dr. Ludlow was born on Staten Island and was graduated from the New York University, and the College of the City of New York. His grandfather was the late S. R. Smith of Staten Island, after whom the S. R. Smith Infirmary, at New Brighton, was named. Dr. Ludlow was a member of the American Medical Association, State Medical Association, County Medical Association, of which he was secretary; County Medical Society, Society Alumni of St. Luke's Hospital, and was attending physician at St. Joseph's Hospital. Dr. Ludlow was one of the most skilful medical stenographers in this country, as well as an able and highly esteemed practitioner. He died in the prime of life, and his death will come to many as a personal loss.

Dr. David L. Wallace, a prominent physician of Newark, N. J., and a member of the Board of Health of that city for many years, died of pneumonia last Monday night, after a brief illness.

Dr. Frank E. Baker, ex-superintendent of the Newark City Hospital, and a practising physician, died in that city March 4, aged forty-eight years. Dr. Baker was a graduate of the College of Physicians and Surgeons of this city.

Dr. George W. Neville, a pioneer physician and preacher, and a Union leader in the days of border fighting, died at Bethel, Kansas, aged eighty-two years. At the beginning of the Civil War he recruited the Second Battalion of Missouri State militia, and in 1862, with 100 recruits, he repulsed an attack upon Harrison Mills, Mo., by 300 of Quantrell's Guerrillas.

Dr. Henry A. Rundlett died last Wednesday at his home, No. 102 Hamilton Place, this city, after a brief illness, of pneumonia. He was born in Chelsea, Mass., in 1856 and was graduated from Harvard University and Medical College. He was well known in the profession in this city, being connected with the German West Side Dispensary and the New York School of Clinical Medicine. Dr. Rundlett was a great friend of the late Henry George, and was one of the speakers at the dedication of the monument to his memory.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, February 20.

A MEDICAL PREMIER FOR CAPE COLONY—THE STATE REGISTRATION OF NURSES—HERBERT SPENCER AS A HYPOCHONDRIAC.

The victory of the Progressive party in the recent elections at the Cape of Good Hope will doubtless place Dr. Leander Starr Jameson at the head of the colonial government. He is doubtless well known on your side of the Atlantic as the "hero"—to use the word in a

theatrical sense—of the Raid. It is now nearly twenty years since he gave up the practice of medicine for the career of a political adventurer under the wing of Cecil Rhodes. He went out to Kimberly in 1878 not, as the legend is, for the sake of his health, but in pursuit of an opportunity of establishing himself in that place as a physician which unexpectedly presented itself. He was very successful and his name became so widely known through South Africa that, by an irony of fate, he was once called in to treat President Kruger. At Kimberley Jameson became intimate with Rhodes who had been condemned by his English physicians and who went to Africa to seek a respite from what was believed to be imminent death. In course of time as the horizon of a new life opened up before him Rhodes induced Jameson to become Administrator of Mashonaland. I need not rehearse the oft-told tale of the Raid and the imprisonment that followed. Jameson himself has said that he made a mistake and paid the penalty. But it cannot be forgotten that his country also suffered grievously for his folly. Unless he has learnt wisdom in the school of experience, his career as Premier of Cape Colony is only likely to lead to fresh disaster, for he is impulsive and headstrong and lacks the qualities that go to the making of a trusty pilot of the Ship of State. As a doctor he had plenty of knowledge but was deficient in judgment; exactly the same may be said of him as a politician. It should be added that he is honest and utterly disinterested. He was the only one of the Rhodes gang who did not amass a vast fortune. This should be reckoned to him for righteousness, for he had every opportunity.

A Bill for the State Registration of Nurses has been introduced in the House of Commons by Dr. Robert Farquharson. It has the active support of two other medical Members of Parliament, Sir John Batty Tuke and Dr. Edward C. Thompson. It was read for the first time on February 15. The object of the Bill is to establish a recognized standard of capability and to prevent any woman who has not reached that standard from calling herself a registered nurse. As is pointed out by Lady Helen Munro Ferguson, in the February number of the *Nineteenth Century and After*, the nursing profession dates from after the Crimean War, when Miss Nightingale organized the first training school in St. Thomas's Hospital. She herself, and Miss Agnes Jones, the pioneer of Poorhouse Nursing, had to find their training in the Kaiserwerth Deaconesses' Home on the Rhine, where the care of the insane and the teaching of children alternated with attendance on the sick. The training organized by Miss Nightingale was more strictly profession in character, and lasted for one year, a period which has subsequently been extended to meet hospital necessities and the growing demands on nurses' skill and knowledge, until to-day no fully trained nurse has had less than two years in a general hospital. Meanwhile the scope of the profession has enormously increased, and some of its latest developments, which bring it into direct contact with the homes of the people, have converted it into a potent instrument of social progress. Mr. Charles Booth states in his book on London that "it is almost true to say that wherever a nurse enters the standard of life is raised;" and he speaks of the advance in this direction as "perhaps the best fruit of the past half-century." The public has not been behind the scientific inquirer in fully appreciating the value of district nursing, and there will soon be scarcely a country town or village without its Queen's or parish nurse, while the quality of the services employed has been considerably raised through the impetus given to the movement by the late Queen Victoria, when she dedicated her Jubilee Gift to the training of highly skilled nurses for the poor. Continued efforts are being made to secure trained nurses for the poorhouses and workhouse infirmaries Certain London schools now employ visiting nurses to inspect and attend ailing pupils, and it may be expected that the Scottish Report on the physical condition of children will lead to further employment of nurses in connection with our elementary schools. In other directions new spheres of usefulness are opening before them. The imperialist wave has swept them into the service of the Empire, and newly formed societies have organized the Nursing Associations for India, South Africa, and the Crown Colonies. While on the one hand the sensitiveness of the public to political and social questions is encouraging the development of nursing; on the other, it is found that the progress of scientific surgery and the increasing numbers of special treatment and curative processes are entailing fresh calls upon the profession and necessitating a rising standard of skill and knowledeg. Yet the profession is still, as regards its internal organization, in a state of chaos. It has no governing body, no standard of training, no corporate existence. Every hospital—whatever its size and standing—is a self-constituted training school. Each works as a separate unit, carries out its own theories of training, and confers its own certificate. A woman who has been two years in a small cottage hospital, six months in a lying-in hospital, or some such specialized institution, will emerge from it as legitimately a "nurse" as a woman who to her three years in a general hospital has added experience in fever and obstetric wards, and passed through the courses of theoretical instruction in bacteriology, physiology, and sanitary science, which form part of the training in many of our large institutions. In these latter hospitals the period and character of the training are more or less assimilated; but even in their case the terms and conditions of service are very varied. Everything depends on the matron. She can curtail or lengthen the period of probation; she can so arrange the work that her nurses will pass successively through the medical, surgical, and other wards, gathering all kinds of experience; or she may so legislate that her nurses will leave the hospital, having seen but one department of work, and remain therefore practically untrained in every other important direction. The certificate earned in either case will be of precisely the same value, will carry the same consideration, and entitle its recipient to the same remuneration. As a result, the prizes of the profession—rich as they are—are distributed haphazard among the fully trained and the partially trained. Private nursing institutions, from which the general public draw their nurses, are staffed with nurses of every kind and degree of training, the one point of similarity being the fees they demand. This state of affairs is unfair not only to the nurses themselves, but to the public. During the late war, when the supply of Army Nurses and their reserves had become exhausted and a call came for volunteers, the absence of a register and the impossibility of discriminating between the qualifications of applicants was a serious handicap, and resulted in the employment of many partially trained nurses, to the exclusion of those who were equally willing and more efficient. The Bill introduced by Dr. Farquharson is intended to remedy those evils. There is, however, very little chance of its becoming law this year. It is to be opposed by the Central Hospital Council for London. That body at a meeting held not long ago at which representatives of all the leading London Hospitals were present passed a resolution to the following effect: "That this council is opposed to any State registration of nurses, and that steps be taken on behalf of the council to oppose any Bill in Parliament having such registration for its object." The case for registration is so

plain and so cogent that it is difficult to believe that this action of the Central Hospital Council is inspired by any higher motive than the wish to prevent interference with the brisk trade which the big hospitals at present ply in nursing certificates. From an economic point of view a uniform standard of professional proficiency would not suit them. It is the old story of "vested interests" which in this country stands in the way of every proposal for reform. There can be little doubt, however, that a State register for nurses will, at no very distant date, be established. The nursing world here is divided into factions which hate each other with all the fervor of rival philanthropists. Another bill having the same object is being promoted by another Society, and the British Medical Association is understood to be considering the whole question. The principle of a measure of such distinct public utility can scarcely fail to be adopted, and when that has come to pass legislation must soon follow.

Much has been written about Herbert Spencer's ill health, and it is certainly wonderful that a man whose physical weakness was so much out of proportion to his intellectual vigor should have produced so much. It appears, however, that he was, at least to a large extent, a *malade imaginaire*. Mr. William Henry Hudson who was for a considerable time closely associated with him in his literary work, tells us that the philosopher's long-continued ill health had hardly any effect on him outwardly. His tall and rather gaunt figure was almost to the last wonderfully erect; his cheeks were always ruddy; his splendid voice—which would have been a fortune to an orator—retained its richness and resonance, his rather rare laugh, its deep-chested musical quality. Few men in the eighties were so well preserved as Herbert Spencer; and it was difficult in looking at him or listening to him to believe that for half-a-century he had been to a considerable extent an invalid. He was often irritable and sometimes quick of temper and of tongue; and he had so little tolerance for the foibles, prejudices and petty absurdities of every-day life that he now and then struck one as hard and even censorious. His irritability had its root in his physical condition. Overwork on his *Principles of Psychology*, which in its original form was published in 1855, brought about a severe attack of nervous prostration from which he never wholly recovered. From that time he was a martyr to dyspepsia and insomnia in their most obstinate forms. He told Mr. Hudson that from the period of his breakdown in middle life he had never known what it was to enjoy a full natural night's sleep. On meeting him in the morning Hudson would ask how he had slept, and the best answer he ever had to give was "I had a very good night for me; I slept four hours." Matters were made worse by his constant recourse to all sorts of soporifics to which he had in the first instance been driven by sheer despair, and which he long employed in quantities which frequently caused his friends alarm. These drugs, while, of course, they did nothing toward the permanent alleviation of the insomnia, undoubtedly aggravated the digestive troubles, while the reaction following their use just as certainly increased the nervous depression and irritability. Another feature of the case, and a very distressing one, was the hypochondria which grew out of these conditions, and which, during the later years of his life, added to the invalid's actual sufferings a variety of imaginary ills. Again and again physicians assured him that the great organs were all sound; he was never fully convinced; and he ultimately got into the habit of watching himself and his symptoms with a morbid curiosity and a minuteness the mental results of which may be readily conceived. Another writer who knew Spencer well, says that "like other valetudinarians he was a somewhat exacting visitor and host. He hated striking clocks, especially those out of doors. When lodging in a village in Berkshire he sent a peremptory request to the owner of the principal house there that the stable clock, which struck the hours, should be at once stopped. When out driving he would, if it occurred to him that he was not feeling well, carefully ascertain the speed of his pulse, and were that not entirely satisfactory would there and then give the order to return home."

PLAGUE IN INDIA.

To the Editor of the Medical News:

Dear Sir: The practical medical man in America will ask but two questions about the plague epidemic in India: (1) Is it likely to spread to the United States? (2) Are suitable measures being taken in all infected ports to prevent rats and other animals from carrying vermin on board ships sailing to American ports, and in general, to prevent the shipping of infected materials?

Considering the distance of India from the United States, and the strict quarantine measures enforced at all American ports, the first question may safely be answered in the negative. To answer the second, would require a thorough knowledge of the difficulties under which the authorities labor in all hygienic matters. The casual observer might readily report that there were very few sanitary precautions taken, either in the city or in the vicinity of the docks where foreign-going ships are loaded. It is true that the quarantine regulations of the United States are not strictly complied with; for instance, on page 16, paragraph 14, of the Regulations, we read: "At ports or places where plague prevails, every precaution must be taken to prevent the vessel becoming infected through the agency of rats, ants, flies, fleas, or other animals. At such ports or places the vessel should not lie at a dock, or tie to the shore, or anchor near any place where such animals may gain access to the vessel. In case cables are led to the shore, they should be freshly tarred and provided with inverted cones or such other devices as may prevent rats and other animals passing to the ship." But any one who cares to visit the docks will find every vessel tied closely to the wharf, with numerous gangways open, and innumerable cables passing from shore to ship, provided with none of the devices suggested above. That there is something very remiss here can hardly be questioned. And the same observer may go into the parts of town where plague prevails, and accompanying the divisional health officer to a tenement where a case of plague has been reported, may see how powerless the officer is, either to compel removal of the patient to an isolation hospital, to prevent a considerable circle of relatives from becoming exposed by proximity to him, or to carry out any disinfection, so long as the patient wills to remain in his own bed. The observer begins to feel that there is nothing to prevent plague from wiping out the population of Bombay and from extending whithersoever it will, by sea routes.

Two facts must be borne in mind to quiet these fears. One is that the inspection of foreign-bound passengers and of their luggage is very thorough, especially in the case of natives or others who have come from seriously infected localities. The process will be described a little later. And the other is that in general, plague shows a tendency to restrict itself to tenement houses which have previously been infected, not often attacking new quarters. And further, that those who exercise proper personal precautions, run comparatively little risk of becoming infected. It is needless to add that those who have been inoculated with Haffkine's prophylactic fluid

are practically safe, even in the presence of a large number of plague cases.

When the disease first appeared in Bombay, late in 1896, stringent measures were adopted by the Government to prevent its spread. Extensive disinfection was undertaken, segregation was compelled under military force in a large number of cases, and other means tried. So strong, however, is the religious hatred of the native, either Hindu or Mohammedan, for anything that seems like interference with his home, that a tremendous feeling of hostility, amounting practically to revolt, was rapidly aroused. The Hindu felt that his home was defiled by the promiscuous entrance of Europeans and servants of low castes. The Mohammedan would far sooner die than be compeled to go to a hospital. And little by little, the stringent measures *had* to give way. Many of them were unnecessary, and others possibly unwise, but at the present, everything that seems like compulsion has been abolished. A single illustration will suffice to show how strong was the feeling of resentment against interference. In one case where it was reported that there had been a death from plague in a certain house, the health officer made his visit, accompanied by the usual squad of policemen, but on asking to see the body, was told that there had been no plague there. The family, known to number eight, were gathered at their meal in full force, and entreated the officials not to come near them lest the meal be defiled. However, as careful search through the house failed to reveal the presence of any corpse or even of a living patient, the inspector approached the family and told them that they must leave the house at once, as it was to be disinfected. Much against their will, seven of the number rose from their seats, while the eighth was now found to be the corpse of the patient who had died of plague, and which had been thus propped up at the meal in order to avoid detection and disinfection.

A sad event in Northern India last year proved to be a great setback to the plague operations there instituted. In one village, after much persuasion, the leading native official had succeeded in getting the people to submit to inoculation, which was done to a large number of persons. It would have been a splendid field for studying the protective powers of the prophylactic, had it not been that within a few days nine persons died of tetanus, evidently contracted through the inoculation. No statement has yet been made public as to exactly where the blame lay, but, of course, the whole country round about became greatly frightened, and no more inoculations could be done for some time. The government of the Punjab, where the accident occurred, has just published the following statement: "The plague measures hitherto adopted have failed to secure the thorough cooperation of the people or to exert much influence on the course of the epidemic. . . . The time has come to cancel some of these and relax the rest. . . . The few necessary and harmless(!) rules which still remain will be enforced strictly, and if necessary, by prosecution, in case of negligent acts likely to spread infection. But prosecutions are to be discouraged. Although early information of the first cases of plague is very important, the compulsory examination of suspected patients or corpses is forbidden, but every person in whose household plague cases or deaths occur, is responsible for reporting these. So soon as the fact is known, information will be spread widely to warn intending visitors of the danger. . . . Evacuation of dwellings is especially advised as soon as nature warns of danger by the presence of dead rats. And if the majority in a village send in a written petition, coercion of the minority may be employed. . . . There is to be no restriction in the future, of the movements of people, with a view to checking the spread of infection by human intercourse, from place to place. There will be no prohibition of railway travel to infected areas and no interference with the travel of persons by road. Railway and road inspections will not be resorted to, and people will be allowed to move about freely in connection with fairs, marriages, and social gatherings. . . . As the religious feeling of the people is opposed to measures for the wholesale death of rats, and as money is wasted without the cooperation of the people, no considerable expense will be incurred along this line in the future."

This government statement has been quoted from rather fully, because it shows so well the way in which, one after another, the authorities of the several infected districts have been compelled to retract from their original position.

The status of disinfection requirements in Bombay and determination of the cause of death in suspected cases, is about as follows; watchmen are appointed at the various burning grounds and cemeteries to give notice of deaths. There are others who are detailed for duty in each district of the city to find out where plague cases have occurred. On receiving a report of a case, the subregistrars, who are qualified hospital assistants, try to get permission to examine the case, during life or after death. If this is not granted, they seek to determine by inquiries, the nature of the case. If it be thought that the case was one of plague, the registrar orders disinfection, and this is carried out either (1) after the case is removed to hospital; (2) after recovery; (3) after the death of the patient, should that occur. In other words, the place may remain without disinfection until the patient recovers or dies. For disinfection, phenyl and acidified bichloride of mercury are used, the furniture being swabbed with the former, and the walls with the latter, the floors being drenched with the same. It is difficult to persuade the relatives to produce any of the patient's clothes for disinfection.

In spite of this enforced absence of stringent regulations, the plague prospects for Bombay are brighter now than in any year of the past seven. Although there were more deaths from plague during the week ending January 19, for example, than in any previous week since last spring, yet it is by looking backward that one is encouraged to hope for improvement. During the week ending January 19, there were 189 deaths from plague, with a total death rate from all causes, of 45.56 per thousand per annum, whereas the mortality figures from plague for the corresponding weeks since 1897 have been 470, 651, 308, 428, 328, 296, 469; and the total death rate for the corresponding week has never been lower than 66.13 since the epidemic started. Just why there has been this improvement it is hard to say, although it is certain that the large number of inoculations done in the past, coupled with the tearing down of buildings unfit for human habitation has been responsible for much good.

If one turns to the inspection of passengers leaving Bombay by sea, there can be little complaint of lack of thoroughness. In the case of Mohammedans, who at certain seasons of the year go in large companies on pilgrimages to Mecca, the requirements are especially strict. The pilgrims are arranged in long lines and individually looked over, all who have fever or other suspicious symptoms being set aside. All who pass this preliminary survey are sent over, in groups of a thousand or so, to a small island in the harbor, where they remain under further supervision for ten days longer, being allowed to embark directly from the island if still free from plague symptoms. All but the newest of baggage is thoroughly sterilized by steam under pressure. Not even first-class passengers are allowed to embark without having been passed by the

medical officer, whose examination need not consist frequently, in any more than a determination that the said passenger has not come from an infected locality and that he has no fever.

In all parts of India, the Government is doing whatever it can, in the laboratory and by personal observation of infected localities, to determine what is the most prevalent method of infection, and to evolve new methods of combating the epidemic. They are now undertaking a series of observations as to the recurrence of plague in infected tenements, even after repeated disinfection, and it is hoped that some facts may be brought to light which will have a practical bearing on the control of the disease.

Edward H. Hume, M.D.,
Acting Assistant Surgeon U. S. Public Health and Marine Hospital Service.
Bombay, India, Feb. 3, 1904.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Regular Monthly Meeting, held December 26, 1903.

The President, Frank H. Daniels, M.D., in the Chair.

Tinnitus Aurium.—This paper was read by Dr. William S. Bryant. So-called tinnitus aurium, he said, may take the form of any conceivable sound, rumbling or pulsating or bell ringing, and in addition to the sound heard there is often an indefinite sense of discomfort within the head. It would seem that these disagreeable feelings cause the proverbial melancholy and irascible temper of the deaf, which by contrast make the blind seem happy. It is generally recognized now that almost any form of deafness or impairment of hearing, is apt to be accompanied by noise in the ears. In nervous individuals the annoying symptoms occasionally become unbearable.

Temperament and Tinnitus Aurium.—Dr. Bryant considers that of late years particularly there has come a very general realization that the effect of noises in the ears are largely dependent upon the individual idiosyncrasy as regards the bearing of annoyances. Very nervous people are not able to stand even slight noises without being so disturbed that they cannot eat or sleep or have any comfort. On the other hand, phlegmatic individuals stand even loud noises without any considerable complaint, and these same patients find that even a little relief affords them so much diminution of whatever annoyance was present that they are very well satisfied. Of course, this same thing is true with regard to other nervous symptoms and the bearing of pain or discomfort generally by nervous people. It will usually be found that if nervous patients do not stand sedatives well, any measure of relief that can be afforded to their tinnitus aurium short of absolute eradication of it, will not seem to them to have benefited them very much.

History of the Affection.—Tinnitus, that is noises in the ear or in the head, was described among the old Greeks by Hippocrates, the father of medicine, and by some of his disciples. Its treatment was then a perplexing problem and it has been so ever since. In recent years otologists have found that it is even more common than was formerly supposed and that very few affections of the ear fail to be unaccompanied by this symptom to a greater or less degree. The diagnosis of tinnitus aurium depends wholly on the statement of the patient, for the symptom complex is purely subjective; there are noises in the ears or in the neighborhood of the ears that may occasionally be heard by anyone who listens for them, but these do not come under the head of tinnitus aurium, which is an entirely subjective phenomena of ringing in the ears.

Etiology.—Tinnitus aurium is due to slight rather than to grave disturbances of the middle ear and is much more common with catarrhal than with purulent inflammation. In most cases the condition is a gradual development of progressive catarrhal or degenerative processes in structures connected with the ear and with the posterior nares. The most important primary cause is either defective nasal respiration, or frank mouth-breathing which excites catarrhal conditions. Not infrequently these seem to be aggravated by some underlying constitutional defect usually spoken of as the gouty diathesis, or considered to be at times some nutritional or circulatory disturbance.

Course of the Disease.—The chapter of accidents which finally leads up to tinnitus aurium practically always begins in infancy and mouth-breathing is writ large on the first page. As the result of mouth-breathing, unfiltered air is carried directly into the posterior fauces and there is caught by the lymphoid tissue consisting of the true tonsils and the faucial tonsillar ring. These microorganisms are usually not very virulent, but they produce low grade inflammatory conditions, commonly spoken of as catarrhal. As a consequence of their presence and the lymphoid reaction against them, hypertrophy of all the tonsillar ring occurs. This is the principal cause for adenoids and is the primary step. While it is usually considered that adenoids are the cause of mouth-breathing, the vicious circle seems to start the other way. The third page of the chapter of accidents that leads up to tinnitus aurium, is nasal deformity with more or less serious obstruction of breathing through the nose and the last page is chronic inflammation of the whole mucous lining of the nasopharynx and middle ear and then surely comes the tinnitus. The conclusion of the chapter is deafness.

Mouth-breathing.—To Dr. Bryant it seems clear that mouth-breathing is generally the precursor and not the consequence of nasal obstruction and it is this perversion of function that causes the local hypertrophy of the lymphatic tissues. When nasal breathing does not continue, the nose no longer subserves its true function and, as a consequence becomes diminished in size, thus keeping up the vicious circle that has been established. Hence the presence of a deflected septum so often in these cases. Because of the absence of function, all the outer portions of the nose do not grow as they should. The nasal septum reaches its normal development, however, and, in order to accommodate itself to its narrowed quarters under the pathological conditions, it must become deflected or bent on itself.

General Conditions in the Etiology.—There is no doubt now in the minds of the great majority of the otologists that many constitutional conditions are responsible for tinnitus aurium. It is not difficult to understand how this is the case. The general conditions most often responsible for it are gout, anemia, cardiac disease, chronic kidney disease, or liver disease and the like. All of these cause a disturbance of the general metabolism, and lessen the resistive vitality of the lymphoid tissues in the throat. As a consequence of this micro-organisms that find their way into the mucous membrane of the fauces, set up low grade inflammatory conditions, which lead to disturbances of the circulation in the mucous membrane of the nasopharynx, the Eustachian canal and even the middle ear itself. Under these conditions microorganisms that enter the respiratory passages with the oral respiratory tide are not properly resisted. When nasal respiration is normal they are strained out of the air and, becom-

ing entangled in the mucous secretion, flow down out of the nose, to do no further damage.

Prophylaxis.—The prophylaxis of tinnitus aurium must be begun early in life and must be directed mainly to the prevention of mouth-breathing and catarrhal inflammations of the mucous membrane of the fauces, especially if anemia or gout is known to be present. For the best results prophylactic measures must begin in early infancy and must be directed from the very beginning to the maintenance of nasal breathing. Children of wealth seem much more likely to be affected with mouth-breathing than those of the poorer classes. Anyone who has studied the habits of the children of the rich, their tendency to talk much and thus keep the mouth open, encouraging mouth-breathing, and to gape at curious things that they are taken to see instead of being allowed to play with playmates in their own way will easily understand this additional frequency. There must be much more attention to somatic conditions in children rather than to the cultivation of intellectual precocity.

Prognosis.—The prognosis of tinnitus aurium depends on the cause to which it is due. Dr. Bryant found from many years of experience in the Massachusetts Charitable Eye and Ear Infirmary, commencing as far back as 1887, that a cure might be expected in every case when the tinnitus was due to some disease of the outer ear alone. A cure might be expected in 50 per cent. and considerable relief of symptoms afforded in the other 50 per cent. when the middle ear alone was affected. When the disease is due to general conditions the prognosis depends almost entirely on the power of therapeutics to control the anemia, the gouty condition or the cardiac disease, to which the disturbance of the ear circulation is secondary.

Treatment.—As prophylactic treatment, Dr. Bryant considers that the most important factor is the removal of adenoids in children, so as to permit of nasal breathing, before the nasal tissues have become so abnormal as to make the resumption of their breathing function a difficult matter. Adenoids should be removed in young children as soon as discovered and whenever mouth-breathing exists the cause should be traced and removed so soon and whenever possible. Conditions very soon become inveterate and then simple operations no longer effect the benefit that they would at the beginning. The treatment of the fully developed condition of tinnitus aurium has in the past covered all the department of otology and nearly all of general medicine. The most important element of direct treatment is to correct all functional disturbances of the ear and its appendages. The complete function of the Eustachian tube must be restored by the use of inflation applications of adrenalin and stimulation with nitrate of silver or electricity. In this matter the otological treatment for tinnitus aurium and deafness are practically identical. In certain cases the tinnitus becomes unbearable because of its severity or the nervous condition of the patient, and patients may suffer very severely from it. Fortunately, in these cases, the condition never lasts very long. Care must be taken in the application of local treatment, since too energetic measures are almost sure to disturb the circulation further and so increase the ringing in the ears. Nor will the reaction after severe treatment always bring benefit.

General Conditions.—When the cause of tinnitus aurium and the subinflammatory condition in the ear structures that is at the base of it, depends on constitutional conditions, then the treatment must apply mainly to these conditions and the prognosis of the case depends on the power to secure relief by medical means. In all cases the general treatment is nearly as important as the local and the treatment of the nasopharynx and of the Eustachian tube is more important than the treatment of the tympanum proper. The fault of treatment generally is that too much attention is paid to the ear and too little to the throat and pharynx. On the other hand, there are supposed to be specific drugs and these are used when general conditions should be treated.

The most important feature of the whole subject is the possible prevention of tinnitus aurium. For this the avoidance of mouth-breathing is absolutely necessary. Animals never breathe through the mouth, except when respiration is very deep, because of recent severe exertion. Anyone who knows much of dogs and horses knows also that if their noses are held they will not open their mouths to breathe until they have to gasp for breath and they almost strangle before doing so. It is important then to train children with regard to mouth-breathing early in life and to make them live a life as much in accordance with nature as possible.

Adenoid Operations and Mortality.—Dr. Putnam said that not long since he had been asked to see a case in consultation in which purulent meningitis had developed after an operation for adenoids. The termination of the case was, of course, fatal. It seems probable to him that there are many more fatalities after adenoid operations than are reported or than there are usually considered to be. Some time ago he saw a similar case in a young adult of twenty years suffering from a typical acute infectious meningitis after operation. It seems not unlikely that in these cases the removal of the lymphatic tissue leaves lymph passages open for the absorption of infectious material of various kinds, which, owing to conditions, is practically always present in the throat.

Specific Meningitis.—Dr. Reynold Webb Wilcox reported a case in which an operation for adenoids was followed by meningitis with all its symptoms of aseptic conditions. Examination of the cerebrospinal fluid, however, showed the presence of the *Micrococcus intracellularis*. In these cases it seems that such microorganisms may be latent, or at least entirely inactive in the lymphoid tissues in the throat and then, after operation, find their way directly into the meninges through the rich lymphatic system which exists in this region. In this case there were no ear or nose complication and no possible question of the diagnosis which had been made by strict bacteriological methods.

Endocarditis After Adenoid Operations.—Dr. Coley said that he had been asked to see a case of endocarditis which occurred after an operation for adenoids. He knows of the occurrence of two other cases in which septic infections of serous membranes followed a successful operation for the removal of the over-grown adenoid tissue. He considers that physicians should recognize that there is always a certain amount of danger after an operation for adenoids and that patients should be forewarned of this and in the case of children the parents should be given some hint of the possibility of septic conditions.

Adenoid Operations at Home.—Dr. Daniels said that to his mind the principal danger in adenoid operations consisted in their performance in the physician's own office and then their walking home shortly afterward through the streets where the dust is almost sure to contain infectious material. It must not be forgotten that there is a large open wound and that air necessarily passes over it. Dr. Daniels considers that the operation should never be done in a physician's office under any circumstances and considers that the taking of this precaution has had not a little to do with his excellent result.

Use of Bromides.—Dr. Bryant, in closing the discussion, said that not infrequently he found the bromides of service in lessening the amount of discomfort occasioned by the tinnitus aurium. Patients who are very nervous, however, sometimes do not react well to sedatives and usually these are the patients who are most bothered by even slight amounts of ringing in the ears. Where the bromides will allay the nervousness there is marked improvement under their administration. In all cases it should be remembered that the underlying conditions, whether it be the gouty diathesis or pure anemia, or defects of the circulation, or congestion of mucous membranes all over the body, as from cold, the general treatment is more important than the local treatment.

Successful Therapy.—Success in the treatment of tinnitus aurium depends not a little on the temperament of the patient. If the sufferer is easily irritated and unable to stand discomfort well then the outlook is very unfavorable for any relief. Under ordinary circumstances, however, relief can be afforded in the vast majority of cases. Dr. Bryant considers that it is a very fortunate thing that his paper should have brought out in the discussion the question of the dangers involved in the removal of adenoids from the throat in certain cases. The operation is by no means so trivial as it is often considered and failure to take proper precautions by careful cleansing of the throat for days beforehand and the avoidance of infectious inoculation afterward may have the most serious consequences. It must not be forgotten that in these cases of enlarged tonsils and hypertrophic adenoid tissues microorganisms have been caught in large abundance in the lymphoid tissues. Owing to conditions they are destroyed at once, but lie more or less dormant for some time and consequently are ready to be absorbed as soon as the operation for adenoids is performed. The emissary veins and the rich lymphatic connections between the outside and the inside of the skull at this point makes any such infection particularly dangerous.

NEW YORK ACADEMY OF MEDICINE.

Section on Genito-urinary Surgery.

Stated Meeting, held January 20, 1904.

The President, James Pedersen, M.D., in the Chair.

Case of Carcinoma of Retained Testis.—Dr. Sinclair Tousey presented this specimen and reported the case.

Dr. Ramon Guiteras said he had had but one similar case, the retention occurring within the inguinal canal. The case terminated fatally. He had had a number of cases of retained testes occurring in different positions and only one proved malignant.

Dr. Howard Lilienthal said he had a case of sarcoma of retained testis which would be reported in his paper.

Dr. Pedersen referred to a case on which he had operated two or three years ago, the details of which were reported at the time. The patient when fourteen years old had received a blow on the left testicle which had driven it out of the scrotum and up to a point apparently just within the internal abdominal ring. He gave the matter no attention until fourteen years later, when he complained of pelvic pain and disturbances of the bladder and rectum. It was at this time that he came under observation. The tumor was about 8 inches long and 4 inches in its widest diameter; it was wedged between the bladder and rectum. A secondary process involving the retroperitoneal glands extended upward along the blood vessels, as in Dr. Tousey's case, and could not be removed. The main tumor was removed and the patient made a good recovery. He was comfortable and relieved of his symptoms for four months. He died cachectic at the end of seven months.

Dr. Sinclair Tousey, in reply to Dr. Van der Poel, said that the patient gave a history of severe pain in the back and then there suddenly commenced a distention of the abdomen very similar to ascites resulting from an enteroptosis. During the course of treatment, when the distention subsided, there was still present a large tumor in the abdomen which was much larger than its present size, the cystic portion being twice as large as the solid portion. The patient then presented the appearance of a woman with a large uterine fibroid.

Small Lipoma of the Cord.—Dr. Ramon Guiteras presented a specimen of a small lipoma of the cord which he had removed during the course of a hernia operation. He said they were frequently met with during hernial operations, but did not think that they possessed any particular significance. He presented the specimen chiefly for the reason that there was found at one end of the lipomatous mass a hard nodule which felt as though there was a small concretion in the mass. After excising the lipoma he incised the nodule and found simply hard tissue which he thought to be a fibrolipoma of the cord.

Dr. Howard Lilienthal said he did not believe lipomata of the cord to be especially rare and, contrary to what had been stated, he believed this was a very important matter because it was not infrequently a direct cause of the hernia; if the cord was in proper position the growth of the mass distended the canal and permitted a hernial protrusion.

Dr. E. L. Keyes, Jr., said that Dr. Alexander presented to the section a man upon whom he had operated some months before for a fibro-lipoma of the cord, so diagnosed by the pathologist. The patient had recurrences and the case proved to be apparently a malignant growth. At the time of operation the whole inguinal region was solid with the tumor which was evidently growing up into the pelvis. He said it would be interesting to know if this tumor gave evidences of malignancy.

Dr. Guiteras said he had seen a number of cases of lipoma of the cord in performing hernia operations, but that he had never seen such a hard nodule in the lipoma and he presented the specimen in order to obtain the opinion of the section regarding its nature.

Prostatic Douche Tube.—Dr. Ramon Guiteras presented this instrument, which consisted of a simple tube having an inflow and an outlet connected with the main tube. It was shaped like a sound, was hollow and had in it four slits near the end which were for the escape of the irrigating fluid. The proximal end of the instrument was connected with the douche-jar and any solution one cared to employ ran through the tube. When the end of the tube was in the bladder beyond the sphincter the prostatic urethra was douched and the fluid would go into the bladder. When the patient's bladder became distended after douching the prostatic urethra the fluid then would escape alongside the tube. If spasm existed and there was a tendency to expel the fluid from the urethra with force the grasp was relaxed on the outflow tube which acted as a vent and resulted in taking off the pressure. In cases of chronic posterior urethritis the instrument worked very well, especially when there was an associated chronic prostatitis when massage of the prostate had been done. He thought it might have been better to have a double current tube, and so he had had made another tube. There was a small tube running through the main one, and, near the end, there were four slits, one on each side. The water or irrigating fluid escaped along the sides.

Dr. John Van der Poel thought that, in some cases, it might prove to be a very useful instrument, especially

where one wished to irrigate the posterior urethra and the bladder at the same time with some solution so weak that it would not have a deleterious affect on the anterior urethra. As a rule he followed a different method because he had never found that passing such an instrument in these cases necessary. He emphasized the importance of not using strong irrigating solutions. His method ordinarily had been to inject the anterior urethra from the meatus with a weak solution of cocaine or eucaine; then with a Janet or Janet-Frank syringe he introduced the fluid into the bladder from the meatus, and allowed the patient to pass it out afterward. If the mucous membrane anterior to the cut-off muscle was sufficiently anesthetized when the fluid entered the urethra it would usually cause a relaxation of the cut-off muscle and no trouble would be experienced in getting fluid into the bladder. Success depended much upon anesthetizing properly the mucous membrane, covering so to speak, the anterior surface of that cut-off muscle. He had treated many cases of gonorrhea, where he had found it not at all necessary to anesthetize the urethra, especially subacute and chronic cases.

Dr. Pederson thought it significant that this means of irrigating the prostatic urethra had not produced epididymitis. He believed that certain cases of chronic posterior urethritis and chronic prostatitis have a patulous condition of the ejaculatory ducts and he has felt that any form of irrigation under these conditions is likely to excite epididymitis. He confessed to some timidity in applying irrigation to the posterior urethra in these cases, even by means of a soft rubber catheter.

Dr. John Van der Poel said that in chronic cases he had never seen an epididymitis or an orchitis arise when the irrigations were given as he had indicated. He had seen such occur when there was an acute anterior urethritis, but the number of cases of epidymitis in acute disease were far rarer, according to his observation, since he had used this method.

Renal Decapsulation in Chronic Nephritis.—Dr. Ramon Guiteras read this paper and said that what he had to present was largely from two papers that had already been published. It was only within a comparative recent period that the kidney was considered a field for surgical treatment, as formerly it had belonged to the domain of the physician. Since Simon classified the surgical diseases of the kidney, the onward strides in kidney surgery had kept pace with the advances of surgery in other fields. Among the first suggestions for the operative treatment of nephritis, was one from Harrison who reported three cases of albuminuria which were cured by incising the parenchyma of the kidney nephrectomy, and he attributed his success to the relief of the increased renal tension which accompanied the nephritis. These cases were supposed to have been operated upon for albuminuria, although the real causes were suspected surgical conditions. One was operated upon for a suspected renal abscess and the other two for supposed stone. After the operation, Harrison was surprised to learn that the albumin had disappeared from the urine. This report really showed the possibility of this operation. Newman, of Glasgow, did nephropexy for torsion of the renal vessels in patients having albuminuria and cylinduria, and in both of his cases the albumin disappeared after the operation, although Dr. Guiteras did not think much importance could be attached to this, as they were probably both cases of movable kidney with congestion and interfered renal function. A number of cases of nephritis with hematuria and nephralgia he said were operated upon by nephrotomy by other surgeons, but in most of these cases it was thought that there was some surgical condition of the kidney present, such as stone. With such cases, there had been noted an improvement in the condition of the urine, the pain and hematuria being relieved. In these cases, the operation was nephrotomy. In a collection of 25 cases operated upon for these symptoms, in 11 the kidney was removed with two deaths, and in 14 others in which nephrotomy was performed, there were two deaths. All these cases were unilateral and the operations were done for some supposed surgical disease of the kidney. It was afterward found that the albuminuria and casts disappeared from the urine and the patients were much benefited in all the cases. He said that, according to Israel, nephrotomy was indicated in cases of chronic nephritis only when there was hematuria, a nephralgia, or both. He then briefly reviewed the mechanism of the manner in which relief or cure was effected and stated that Isreal's work was of great importance in renal surgery. He said that in 1899, Furgeson, of Chicago, wrote a paper and expressed the opinion that chronic nephritis should be treated on surgical principles, such as controlled inflammations in other parts of the body. To Edebohls belonged the credit of attempting to operate upon the kidneys purposely for the cure of Bright's disease. In his first contribution to this subject, the operative treatment of chronic nephritis, Edebohls reported 18 cases, 14 being bilateral and four unilateral. The examination of the urine, the previous history, and the appearance of the kidneys, were the chief factors in making a diagnosis. In 16, the operation was nephrotomy, 11 were bilateral and five unilateral. Dr. Guiteras then briefly review Dr. Edebohls' method of performing this operation. In the two remaining cases, he stripped the capcule entirely from the kidney, did not fix it to the abdominal wall, but replaced it in the fatty capsule. This operation is since known as Edebohls' operation for chronic Brights. Among Edebohls' 18 cases, the right kidney was affected in four cases, the left alone in four cases, and both kidneys in nine cases, while in one case the unilateral or bilateral nature of the case was undetermined. There was no mortality among these 18 cases. In six of the eight cases in which the chronic Bright's disease was unilateral, the healthy condition of the opposite kidney was confirmed at the time of the operation. Summing up the results, Edebohls found that in eight cases which were observed for a sufficient length of time, the albuminuria and casts disappeared in from 4½ (the shortest time) to twelve months (the longest time). It was concluded that chronic Bright's disease was amenable to operation, although he did not state that all cases could be cured in all stages. Dr. Guiteras then offered an explanation of the relief which followed decapsulation. This operation resulted in the formation of adhesions and the growth of new arterial vessels supplying the kidney and contributing to the regeneration of the but little altered parenchymatous elements, as well as to the absorption of interstitial exudates, etc. In this respect Edebohls' operation differed from that of Harrison; the latter did the operation of nephrotomy to relieve tension and cure what he suspected to be a suppurating kidney and nephrolithiasis, while Isreal performed the operation of nephrotomy to relieve congestion and in this way cure the patient of a neuralgia and hematuria; and from Pousson and others who operated for the same purpose. The question of bilaterality and unilaterality of chronic Bright's he said was fully solved and the opinions so far expressed that Bright's disease is unilateral, have not been backed by observations. He believed that, in order to have a true nephritis, it must be present in both kidneys, and it is a fact expressed by the pathologists that such changes occur in both organs, although they may vary in their course. He stated that among 500 autopsies made on those who had died of chronic Bright's disease, there was not one in which the

disease could be truly considered unilateral and only 14 where one kidney was more involved than the other. The next question to be considered was the correct diagnosis of nephritis and also how to differentiate between the various types of the disease upon inspection of a decorticated kidney. This was very important: any one who was experienced in post-mortem work must acknowledge the difficulty encountered in determining the pathological condition of the kidney by inspection and palpation of that organ either before the capsule is removed or afterwards, or even from the condition of the fatty capsule or the capsule propria. He said that Isreal had made the statement that chronic nephritis was more difficult to distinguish in the living, even after splitting the kidney, than in the dead. An examination of the capsule did not give an idea as to the condition of the kidney. This may be removed easily or with difficulty. At times there was found such a close relationship between the two capsules that they could not be separated on account of adhesions to one another. Furgeson, of Chicago, incises a piece of the renal tissue in order to facilitate diagnosis. The only procedure which would give a correct diagnosis he believed was to incise and remove a V-shaped piece from the cortical and pyramidal portions and make a microscopical study of it. He said that many cases of albuminuria and cylindruria were not, properly speaking, cases of Bright's disease. For example, a movable kidney may cause such a condition due to increased tension in the renal vessels as well as to the backward pressure upon the kidney of the urine through a kinking of the ureter. By performing a nephropexy the albumin and casts would disappear. If this disturbance in the circulation and function of the kidney was kept up long enough, a secondary nephritis might take place. He said that a nephritis of both kidneys might occur even when but one kidney was movable. In such an instance, a nephropexy might improve the condition and stay the process although it would not cure disease, if a true nephritis existed where certain pathological changes had taken place, and restore fully the function of the kidney as shown in the elimination of solids. He said Pousson claimed that the sympathetic relationship between the kidneys were somewhat similar to the relationship that existed between the two eyes and oftentimes operations upon one would relieve the same condition in the other. A time when the operation was considered to be imperative of course was when the patient was passing very little urine or none at all. He instanced a case by Whitacre, of Cincinnati, in which there was anuria, decapsulation of the kidney was followed by a return to the normal amount of urine passed in twenty-four hours. This patient was restored to perfect health Marx, of Kansas City, had also met with similar success. Rocky, of Portland, Oregon, operated upon a case of anuria, but the patient died of uremia. Freeman operated upon a patient who was passing a fair amount of urine and who was in good condition, but this patient died eighteen hours later of suppression. Gibbons, of Scranton, operated upon a case of Bright's, passing a fair amount of urine, and this patient died of uremia five days after the decapsulation and fixation of one kidney. After reviewing reports of such cases in which decapsulation had been performed, he said that no conclusions could be drawn, for we knew that decapsulation would cure anuria in some cases, while it induced it in others.

It was his personal belief that a chronic diffuse nephritis was the most unfavorable condition for operation giving a 75 per cent. mortality, although many of these patients were operated upon who were *in extremis*, some of them suffering from general anasarca to such a degree that after decapsulation, they drained for several days out of the incision in the lumbar region. He said that the benefit from the operation seemed to be from increasing the circulation within the kidney and that the circulation was increased by the formation of adhesions which brought a new fluid supply through these vessels. Some physicians argued that this increased circulation in the kidney could be compared with that in the lungs, *i.e.*, the anastomosis between the bronchial and pulmonary vessels. It was still a question with him whether it was better to decapsulate the kidneys partially and make them fast to the abdominal wall, or to fully decapsulate them and have them returned to their fatty capsule. He felt that the former method was the one of choice because of the firm adhesions which he had seen between the kidney and the abdominal wall, and the scant vascularity of the fatty capsules. It was not known just how much blood came from the fatty capsule, although Edebohls, at the Washington meeting of the American Association of Genito-urinary Surgeons, last year, had stated that he had seen in a recent autopsy quite large blood vessels which had penetrated the renal tissue through the newly formed capsule propria from the fatty capsules. Johnson, of San Francisco, experimented on dogs and attempted to show that the blood supply from the fatty capsule was very meager. Johnson had stated that the renal capsule consisted of two layers, the outer of which was the thicker. In decapsulation, it was the outer one that always came away, leaving the inner one lacerated but adherent. After decapsulation, a thin exudate appeared upon the surface which soon became a fibrous investment resembling the normal capsule in that it stripped readily, although it continued to grow thicker and more and more fibrous. In no case was there any considerable anastomosis between the renal and perineal blood channels. Even if the relation of the dog's kidney to the surrounding tissues was not the same as those in man, he said it was still probable that the reconstruction of the capsule was the same, and this reconstruction might indicate a renewal of the kidney tension in two months when the new capsule is thicker than the old, and recurrence of the symptoms in three and a half to four months when the new capsule is fully developed, and it might also account for the deaths that occurred after this period. Until there had been longer periods of observations he said that one might continue to think that when the new capsule forms, there will be a contraction with a diminution of the blood supply to that organ. The only chances of improvement after decapsulation would result from a period of freedom between the stripping off of the capsule proper and the consequent contraction of the new formed capsule.

It seemed to him that in cases of chronic Bright's disease, one should carefully study the conditions before advising operative procedures, and so long as the patient was fairly comfortable and getting rid of a sufficient amount of solids and doing well under dietetic treatment, waters, medicines, climate, etc., he believed such patients would do well without operating. If later the process advanced rapidly and there was fear of the heart action becoming impaired, he thought the time had arrived when operative interference should be advised. Some recover perfect health after operation, while in others the edema may persist. The urine is said to return to its normal condition in many cases, particularly in those in which the kidney was movable. He said it was interesting to know what operators mean when they say the urine was normal after the operation, whether it referred to the absence of such pathological manifestations as albuminuria and casts, or whether it referred as well to a return to the normal percentage of solids. In a number of cases the albumin and casts disappear after operation, while in others the albumin and casts persist, although less marked. Again, some pa-

tient showed no improvement at all in the condition of the urine. The best results in this line of work had been obtained in cases of movable kidney in which the albumin and casts were the only evidences of a Bright's disease, disappeared after the decapsulation. The statistics of 120 cases showed 16 per cent. cured, 40 per cent. improved, 11 per cent. unimproved; and of this list there were 33 per cent. deaths. These statistics were taken from an article read in Washington and were the result of a review of the literature and the answers of circular letters upon this subject. In cases of interstitial nephritis, he said the results appeared to be brilliant, when the albumin and casts disappeared from the urine, although the amount of solids secreted were not brought down to the normal. The mortality in cases of chronic interstitial nephritis unfortunately was 26 per cent.; in chronic parenchymatous nephritis it was 25 per cent.; in chronic diffuse nephritis 75 per cent. The results obtained were those computed by the reports of different men. The operation of decapsulation of the kidney for the cure of chronic Bright's he said was a new procedure and one that as yet had not been fully threshed out.

Dr. Ramon Guiteras said that many medical men now looked with favor upon the operation. He said that at the annual meeting of the Pennsylvania State Medical Society, Dr. Tyson read a paper on this subject; he and most of the men who discussed the paper expressed their belief in the operation. He said that many of the leading physicians in New York advocate the operation, as was evidenced by the discussion of the subject before the Society of Greater New York.

Dr. George M. Edebohls said that the subject under discussion was such an extensive one that it could not be properly gone over in a reasonably limited time. All were very much indebted to Dr. Guiteras for his untiring efforts in collecting such valuable material in such a painstaking way and analyzing the situation for the profession as he did in his paper to-night and in other contributions. He said that Dr. Guiteras had practically given them the substance of two papers previously published, giving the pros and cons, and these he had thoroughly ventilated. Dr. Edebohls said he himself had kept on with the work and was at present busy making a thorough investigation of the after effects and results of renal decapsulation for chronic nephritis. Even now there was sufficient material to enable us to speak of the immediate results of the operation, and he believed that very soon one would be able to state positively that a given case of nephritis gave a prospect of relief, improvement, or cure from the operation of decapsulation, or again that the idea of any operative measure had better be abandoned. To illustrate he referred to a man, thirty-five years old, who had nephritis for three or four years. One and a half years ago his physician called his attention to the possibility of relief by operation, but he decided to wait until he could learn more of the results. He waited, and while waiting retinitis albuminurica developed. Now, statistics show that 67 per cent. of cases of chronic nephritis live less than a year after retinitis aubuminurica becomes established. When the patient was told this he was ready to resort to any measure that offered him hopes of a longer life and asked for operation. The oculist told him it was too late, and his family physician that it was too early for operation in his case. Here were two directly clashing opinions which showed that the operation is looked upon from two widely different standpoints.

Dr. Edebohls said that he believed as soon as the clinical evidences established the fact that we were dealing with a case of *chronic* nephritis, then was the time to operate, for patients, under such conditions, always do better with the kidneys decapsulated. That was the sum and substance of his position at the present time. He emphasized the importance of keeping under observation all patients who had been operated upon. At the time he published his first paper on this subject he reported 19 cases, out of which number he had then lost traces of but 3; with the exception of these 3, lost sight of long ago, had been able to follow to date every patient he had operated upon, his cases now numbering 73. He said he was just about concluding the investigation to date of these seventy cases with a view to early publication of the final results. In this paper he intended giving a résumé of the entire work done so far, and throwing what light he could upon what could be expected from the establishment of a collateral renal circulation. He had had three opportunities to operate a second time upon kidneys upon which a prior operation had been performed, and in each operation he had found large blood vessels, all pumping blood toward the kidney, so large that at the second operation a large number of ligatures were required to control the bleeding. That gave him the idea that the increased blood supply to the kidney was the reason why kidneys the seat of nephritis were improved after operation. He said the clinical results had proven to be satisfactory, and this being so we could afford to await the full explanation of the *modus operandi* which the future would bring. He said that quite a number of observers had investigated this point, experimenting upon dogs and rabbits, and the majority of them had agreed that there was an abundant collateral circulation established, some of the new formed vessels even passing to the depths of the kidney substance and the papillæ.

Dr. Edebohls knew of only three observations of the human kidney as observed post mortem some time after renal decapsulation. Jewett, of Buffalo, had reported one, and although he failed to note any considerable new circulation, his publication fails to carry the impression or conviction of a thorough study having been made. In a second case, published by Cutler, of Boston, no mention is made of the presence or absence of a new circulation. The third was a case of his own, the patient dying of pneumonia four months after bilateral renal decapsulation. Dr. John H. Larkin, of the Pathological Department of Columbia University, had removed both kidneys in connection with their surrounding structures. A careful and painstaking study of a large number of serial sections, soon to be published in detail by Dr. Larkin, had established the fact of the formation of numerous new blood channels between the kidney and the tissues surrounding it, especially the perirenal fat. He said that Dr. Guiteras and himself had early in 1902, and independently of each other, studied and recorded the early history of the development of the surgical treatment of nephritis, and that the facts in relation thereto as detailed by Dr. Guiteras in his paper of the evening were substantially correct.

Dr. Howard Lilienthal said he had never performed this operation although he had watched with much interest the work of others. From the report of the cases by Dr. Guiteras he said it struck him that improvement came on too soon after the operation if that improvement was supposed to be due to the formation of a new anastomosis. One, two, three or four days he believed to be too soon to expect new vessels to be formed.

Nephropexy.—Dr. Berg reported a case upon which a nephropexy had been performed according to the method of Edebohls two years ago; about two weeks ago a second operation was demanded on account of a resinking of that organ. At the time of operation a very careful note was taken regarding the

condition of the blood vessels, their number, etc. He found that the fatty capsule was not more vascular that it was at the time of the first operation. He thought that possibly some might have been present at the lower pole of the kidney but none passed from the capsule proper into the kidney tissue itself. When incised there was no bleeding whatever. It was a perfectly dry condition.

Dr. Edward L. Keyes, Jr., said he had not performed this operation of decapsulation except in one instance, and there was nephroptosis and catarrhal pyelitis with attacks of renal colic. The kidney was stitched in proper position and then the albumin and pus disappeared from the urine. In three other cases operation had been performed for suppuration in the kidney; besides this suppuration there was chronic interstitial nephritis. In two cases the kidney was incised under the impression that stone was present, but none was found although in one there was found a hard nodular scar suggesting the previous existence of a stone. In both these cases in which the kidney was incised the casts and albumin disappeared from the urine after the operation. One of these cases was followed but a few months, the other about five years. In another case a stone was supposed to be present; both kidneys were incised after splitting the capsule and even needles were stuck into the kidney in search of stone, but none was found. After this maneuver the albumin and casts disappeared from the urine. This was certainly two years ago, and the urine remained free from evidences of inflammation. What caused the relief he could not say. He said he had only once cut down upon a kidney after nephrorrhaphy had been done and he had found dense scar tissue, but in no place was it filled with blood vessels.

Dr. John Van der Poel said that he had been given an opportunity of examining a kidney three weeks ago after partial splitting of that organ and search for stone had been performed. The adhesions which had formed were quite dense, more so than one would suppose, and were well formed. Like Dr. Lilienthal he had never had the opportunity of splitting the kidney for nephritis, but he would do the operation when the opportunity presented itself, especially after hearing the results that had been obtained by Dr. Edebohls and Dr. Guiteras. He believed this operation appealed to the surgical more than to the medical side of the profession. The medical profession were, as a rule, loath to allow the patient to fall into surgical hands until the operation was more definitely and better understood. Medical cases at present were not, as a rule, transferred from the medical to the surgical wards until certain evidences of so-called surgical complications appeared, that is, pus in addition to the albumin, and casts. When the results of the operation were better understood by the profession at large it would give surgeons more opportunities for satisfying themselves regarding the true merits of the procedure.

NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

Regular Monthly Meeting, held January 14, 1904.

The President, David Bovaird, Jr., M.D., in the Chair.

Diabetes Insipidus.—Dr. E. S. Sill presented a case of diabetes insipidus in a child of six years. According to the mother's reports when the child first came under observation, it was passing five to twelve quarts of urine in a day. During the last three or four days this quantity has been reduced to about eight quarts per day. The patient perspired very little, the mouth was constantly dry and there was an almost constant thirst. The urine was of pale straw color, specific gravity 1.005, containing in the twenty-four hours from eighteen to thirty grams of urea. The child is being treated with fluid extracts of ergot, fifteen minims three times a day and is apparently improving. Altogether some eighty-one cases of this affection have been reported in children. The most important element in the history is heredity, the patients usually coming of highly neurotic parents. It occurs much more frequently in males than in females. In one case the etiological factor seemed to be the drinking of large quantities of ice water. In a certain number of cases lesions of the solar plexus were found. Syphilis was suspected in a number of the cases. An interesting effect of diabetes insipidus reported by several observers may be a retardation of growth. No other abnormal ingredients are ever found in the urine and sometimes the only symptom present is the passage of large quantities of water. At times the diagnosis may be made by the harsh dry skin and the rough feel of the integument.

Prognosis.— The prognosis of the disease as regards life is good, though the affection is usually chronic. Out of 77 cases followed for a number of years, 16 recovered and 14 proved fatal. Forty-seven of the patients improved either as the result of treatment or nature's effort to restore proper metabolism. In children particularly the thirst becomes insufferable if water is kept from them and, in a number of reported cases, they have, when confined in rooms, drunk their own urine. This is, however, as a rule, only very slightly different from water. The children are usually nervous and there is a history of nervous symptoms of other kinds before the development of the diabetes insipidus. Besides the ergot, valerian is said to be of service in the treatment of the disease, especially in the form of valerianate of zinc.

Dr. Sarah Welt Kakeles reported two cases of diabetes insipidus that had been under her observation in recent years. The first occurred in a girl 9½ years of age, who seemed perfectly healthy except for this symptom and who was under observation for three years. During this time nearly every drug that might possibly help the condition was tried except opium and atropine, which have, in Dr. Kakeles' opinion, a constitutional effect that is very undesirable in children. The only drug from which any satisfaction was obtained is antipyrin. The child passed from under observation for a time and later developed oculomotor palsy with distinct ptosis. Nine months later, she was found to be suffering from true diabetes mellitus. The second case was a boy of about five years of age who was passing about ten or twelve quarts of water a day. When it is remembered that this represents from 20 to 25 pounds and the boy weighed not much more than 40 pounds, and that therefore he was passing two-thirds of his weight in urine every day, some idea of the disturbance of metabolism can be appreciated.

Diabetes Insipidus Under Two Years of Age.— Dr. James J. Walsh reported a case of diabetes insipidus occurring in a child aged about eighteen months. The little one, who came from a very nervous family, was strong and healthy-looking, but fell out of bed one morning and during the next day or two developed frequency of urination and an almost insatiable thirst. Examination of the urine showed a specific gravity of 1.003 with no albumin and no sugar. It was hard to decide how much urine the child was passing, as it was usually passed in the napkins that had to be worn, but a conservative estimate seemed to be between five and six quarts. The little one could not talk, but soon made its desire for water known by making a clucking noise with the mouth and insisted on being given to drink many times during the night. In this case the symptoms gradually subsided and after about three months seemed to

disappear entirely. Since then there has been no recurrence.

Addison's Disease and Frequency of Urination.—Dr. Charles Hermann reported a case of Addison's disease in which the most prominent symptom at the beginning was marked frequency of urination. Other symptoms, however, called attention to the condition of the suprarenal bodies and suprarenal extract was administered. As a result the frequency of urination gradually disappeared. It seems possible that the suprarenal extract may be of service in the treatment of diabetes insipidus.

Bronchopneumonia.—Dr. William P. Northrup read a paper on the course and symptoms of bronchopneumonia. There are three forms of the disease, according to the three forms of resistance which are found in the human being. The first is hypostatic pneumonia, which occurs in the least resisting and in children, particularly in marantic patients. Then there is the true bronchopneumonia, in patients who are more resistant but who are handicapped by the existence of some previous affection or condition. Finally, there is lobar pneumonia, a true primary disease, usually benign and in children is the pneumonia of the better class of practice. Hypostatic pneumonia is one symptom of approaching death. Bronchopneumonia usually occurs after infections, but may occur after nasopharyngeal catarrh or after colds and the like, which are usually but wrongfully considered not to be infective. During the last three years Dr. Northrup has seen 167 cases of primary bronchpneumonia in the autopsy room. None of these occurred after any of the exanthemata. Most of them develop while the children are under the care of foster mothers in the tenement houses and the previous course of the case could not be learned. It is the exception, however, in autopsies on children to find the lungs entirely free from pneumonia lesions, even where the death is from some other cause. One-third of the cases of bronchopneumonia are said to be primary, but this is too small a proportion for institutions. It must not be forgotten that acute coryza tracheitis, or cold with fever, may precede the pneumonia and then of course the affection must be considered secondary and not primary.

Seasonal Incidents.—Two-thirds of the cases occur between December and May. The male patients suffering from pneumonia, compared to females, are as five to four. It must be remembered, however, that there are more males than females in foundling asylums. Seventy per cent. of the cases observed occur under two years and it is evident that changes in the weather with the production of the slight infectious diseases known as colds and extension of this process into the lungs is responsible for the pneumonia. Vomiting occurred in only six out of 26 cases carefully noted for this symptom. Chills occurred in but two cases. The respiration is frequent, but so also is the pulse and the respiration. A very characteristic symptom is the cry with an abrupt end due to the fact that the child suffers when it uses its lungs to expel air. In a word there is expiratory discomfort. This is probably what causes the characteristic grunt which experienced nurses look upon as an almost infallible sign of pneumonia. Pulse respiration ratio is, of course, disturbed. Usually it is about one to three in bronchopneumonia, though the respirations may become so rapid as to be one to two.

Physical Signs.—On inspection there is an almost characteristic retraction of the upper parts of the lungs. Percussion does not give much information, but because of its value in lobar pneumonia it is looked upon as one of the most important physical diagnostic methods. Auscultation discloses subcrepitant and fine râles over the affected area. This is practically conclusive proof of the existence of pneumonia. The characteristic symptoms may not be recognized at the beginning. The foci of the disease may be so scattered as not easily to be detected. The development of the disease then must be awaited in order to make the diagnosis.

Duration of the Disease.—The average duration is about thirteen to fourteen days. Some of the milder cases are entirely well at the end of four or five days. The severer cases in weak children may run on for two or three months. These produce chronic changes in the lungs and there is apt to be a suspicion of the presence of the tubercle bacillus. The end is usually by lysis. Crisis is exceptional, occurring only in nine out of 167 cases. Severe forms of the disease last longer and may give such symptoms as Cheyne-Stokes respiration. Cough is apt to be dry, nagging and irritative rather than productive. Gas distention of the abdomen always makes the conditions serious because of interference with respiration and is especially important in weak children and slow running cases.

Differential Diagnosis.—Under three years of age almost any grave illness must be suspected of being bronchopneumonia and care must be taken to exclude it before the doctor's mind is made up. Cough is not essential to the diagnosis and the temperature chart is of very little value, as bronchpneumonia may occur without fever. The most important sign is the disturbance of the pulse respiration. This occurs quite frequently in measles, and measles is apt also to be accompanied by bronchitis, easily permitting a mistake of diagnosis, but it must not be forgotten that measles also not infrequently leads to bronchopneumonia. Scarlet fever is seldom accompanied by disturbance of the pulse respiration ratio. Any infection of the respiratory passages may be followed by bronchopneumonia. A distinction is sometimes made between disseminated pneumonia and capillary bronchitis. The distinction, however, is of no practical value, as it is impossible to separate the two diseases from one another, small foci of bronchopneumonia, being almost surely present and the treatment and prognosis of the two disorders is the same.

Diphtheria and Bronchopneumonia.—Sometimes it happens that bronchopneumonia is diagnosed when diphtheria is the real agent at work. It is the laryngeal stenosis which gives rise to the supposed bronchial breathing that leads to the mistake. This mistake has happened even in experienced hands. Meningitis is distinguished from bronchopneumonia by the comparatively slow pulse, the slow respiration and the tendency to coma. While the shoulders and neck are stiff in pneumonia, they have not the rigidity which is noticed always in meningitis. Meningitis may further be distinguished finally by lumbar puncture.

Treatment of Pneumonia.—Dr. William P. Northrup said that the first principle in the treatment must of course be not to treat the lesion but the patient with the lesion. As bronchopneumonia is usually a secondary disease, the sufferer from it is twice a patient. This secondary infection is due to the fact that the lymphoid tissue and connective tissue in young children is little resistive. Bronchopneumonia should be considered as a pulmonary erysipelas or cellulitis. This thought makes for care in its management by recalling its seriousness and also shows how uncertain the prognosis is. As it is an affection of the lungs it is important that the air that the patient gets should be pure. Only a limited amount of air can be absorbed and that must be capable of doing as much work as possible. Alonzo Clark, who first permitted air to enter a typhus fever ward, had the heroic courage of a magnificent conviction.

Prophylaxis.—Under certain conditions prophylaxis can be more or less assured. Measles is not infrequently followed by diphtheria, and a succession of these

two diseases is almost sure to give rise to some bronchopneumonia. If the diphtheria can be prevented, usually the bronchopneumonia danger will not be so great. Hence measles patients, at least in institutions, should be immunized against diphtheria. During the course of the infectious fevers in childhood, if children are allowed to breathe cool fresh air, a window in their room being open toward the south with the bed in the middle of the room and the eyes away from the light, then bronchopneumonia will seldom develop. When bronchopneumonia itself is severe this same treatment is the best possible fundamental principle, especially in splenic cases. The room may be so cold that nurses have to wear overcoats and gloves. The little patients are not any more likely to take cold than they would be if suffering from erysipelas. Once during the Civil War the hospital in which a number of patients suffering from pneumonia were, was burned down. The papers gave heartrending accounts of the suffering of the soldiers who, in the midst of winter, had to be treated as best they could wherever they could be laid after removal from the hospital. Most of them had no other protection than a canvas spread over some barrels. The papers said that all of them would die. As a matter of fact, they all recovered. This is quite different, of course, from the exposure of a débutante, for instance, who, after breathing the secondhand air of a crowded room with resistive vitality lowered by overfeeding and underdressing, comes suddenly out into the air and thus catches cold. A fever patient will not catch cold in bed.

Water and Unbreathed Air.—Water in small quantities must be given frequently and will be found very conducive to quiet and rest. It will not infrequently be found that this is forgotten or not sufficiently attended to. The physician must protest against the crowding of the patient's room by friends who are depressant rather than encouraging. In a recent case Dr. Northrup found a tearful grandmother, two old women cronies of hers, a gas fixture and a gas stove, four grown sons and a pug dog. Besides this there were two doctors and yet, though the room was not very large, the little patient was somehow supposed to be getting its portion of air.

Drugs.—The first and most important drug is castor oil, as cleansing of the intestines is very necessary. Avoid the use of syrups and all fermenting foods. As has been well said, have air everywhere but not in the abdomen. Whenever there is meteorism, high rectal infusion should be employed, for which warm salt solution is the best. With regard to the antipyretic drugs, none of them will be employed with benefit and all of them will do harm.

Treatment of Fever.—As an antipyretic water should be used with discretion, but the fever is now the main index of the seriousness of the disease, better than a careful theremometric chart is for the physician to stand for ten minutes at the foot of the bed and carefully inspect the patient. Whenever there is restlessness a cold cloth may be applied to the forehead and temples and also to the wrists. This will refresh the patient much better than an ice cap. If the little patient has a plentiful supply of hair the cold from an ice cap will not penetrate very deeply. A polar bear sleeps very comfortably on an ice pillow. Notwithstanding the depressant chronic character of the disease, stimulants are not always needed. The circulation, however, must be maintained. It is always the rule to find children suffering from pneumonia with cold clammy feet, though their head is too hot. Hot footbaths should occasionally be given with great care, the tub being placed under the clothes. An excellent stimulant is a hot saline, which will also promote general comfort.

General Precautions.—Children will be much more comfortable if they are not asked to take food and drink too often, this only disturbs them and rest is extremely important as a part of the treatment, there is almost more danger of overfeeding than of underfeeding. Another precaution is to avoid any constriction of the chest, consequently there must be no poultices and vests and bandaging. These things only serve to macerate the skin and make the child restless. While the child is asleep it must not be disturbed for any reason. Avoid steam and the use of canopies, since they rob the child of oxygen. When pulse and respiration are both very much disturbed and there is a tendency to inflation of the abdomen the feet will often be found cold and the indication is for stimulation. The dusky face with severe coughing may prove to be no more than the effect of cold feet. Whisky and strychnine are the only two drugs that deserve to be mentioned.

How to Kill a Pneumonia Patient.—Directions have been given so often as to how to save a pneumonia patient and consultants so often find these directions glaringly violated that it is thought that perhaps directions how to kill a pneumonia patient may prove of service. Light two or three gas jets in the room and perhaps also a gas stove. Have at least eight friends spend most of the time in the room. Wrap the child up tightly in a poultice, and if the temperature is from 104° to 105° F., renew the poultice and make it tighter than before. Fill the room full of steam, surround the bed by blankets, close the windows hermetically, and then perhaps you have done everything possible to keep the child from recovering from its pneumonia. Perhaps, however, the free administration of some coal-tar products may be suggested as a *coup de grace*.

Hygienic Treatment.—Dr. Emmet Holt said that it is gratifying indeed to hear that the modern physicians are insisting on the hygienic treatment of pneumonia. Students are now taught that pneumonia patients recover and are not cured, though just the opposite teaching used to be the rule. Not all pneumonia patients are in the same class and not all should be treated the same way. A little patient six weeks old with respirations eighty and fine râles all over the chest, wheezing, cyanotic, prostrated, is not in the same class with a patient whose temperature is 105° F. and whose condition is reasonably good otherwise. The old time ideas of stuffing cotton into the windows in order to prevent the slightest amount of fresh air must, of course, be preached and practised. On the other hand cold for delicate patients is almost sure to do harm. It must not be forgotten that it is delicate marasmic children that suffer most from bronchopneumonia and they will not react well to air so cold that the nurses must wear gloves and fur coats.

Steam Valuable Adjuvant.—Dr. Holt believes that steam may sometimes be a valuable adjuvant to treatment, especially in the cases of weakly children. When there is continual irritation and a tight, dry wheezing cough with many râles, then steam is the most efficient agent the practitioner has at hand. Dr. Holt's experience in this matter justifies him in saying authoritatively that steam, far from doing harm is a very valuable factor for the relief of the respiratory symptoms.

Death Rate.—The death rate in institutions is supposed to be more than one-half the patients. In private practice, however, the death rate of bronchopneumonia is not very high. In the last two years Dr. Holt has seen 119 cases, 92 of them in consultation. A fair proportion of them were severe, some of them were actually desperate cases. Seventy were lobar pneumonia and of these 61 got well. Twenty-one of these were under two years of age. As a rule one entire lung was involved in these cases. Forty-eight of the cases were broncho-

pneumonia and 41 of them recovered. Most of the fatalities were under one year of age and a great many under six months. There is evidently a strong tendency to get well except in very young infants.

Feeding After Air.—Next to air Dr. Holt considers that feeding should be emphasized. Be careful of overfeeding early in the disease. There is a temptation to think that the patient is in for a siege of illness and that the more nutrition that he has the better, but this is a mistake. With regard to the reduction of temperature it should be tried only when absolutely necessary and by whatever means causes the least bother to the patient. Especially must there be no rule that whenever the patient's temperature is at a certain mark he must be bathed. If they are sleeping they must not be awakened for any reason. Physicians' children are much more apt to suffer in this matter than others.

What Not To Do.—Dr. Floyd Crandall said that it seems important to emphasize the things not to do in pneumonia. Overstrenuousness must be avoided. It wears the patients out like the treatment of diphtheria before the introduction of antitoxin. Syrups disturb digestion and take away the appetite. The taking of the temperature often disturbs children without giving any very definite information. Especially is this true if the temperature is taken per rectum. Children rebel and cry. Dr. Crandall emphasizes the fact that comparatively few deaths from bronchopneumonia occur in private practice, notwithstanding the expectation in this regard from what is known in hospital practice.

Fresh Air a Panacea.—Dr. Knopf said that he was delighted to find the open-air treatment suggested for an acute pulmonary disease, as it is now so universally practised for chronic cases. In tuberculosis, however, patients are not plunged into cold air at once, but are allowed to grow accustomed to it, the same thing would seem to be eminently suitable for children. One window should be open at a time, so as not to do harm. Dr. Knopf believes that the gentle counterirritation of cupping is a good means of lessening the irritability of pneumonic tissue, especially lessening the congestion at the beginning of a pneumonia, and thus preventing it from being as serious as it otherwise would be. Drugs are not of much importance and yet there must be no therapeutic nihilism. Jacobi has found digitalis good from the beginning. Whisky should be used whenever there is depression. The coal-tar products have killed many patients. It must not be forgotten that the creosote ordinarily employed is a coal-tar product.

So-called Primary Bronchopneumonia.—Dr. Chas. G. Kerley said that so-called primary bronchopneumonia often follows a cold. This must be remembered for the treatment of ordinary bronchitis in young children must always be considered important. No bronchitis should ever be called mild because children are so lacking in resistance. Reduction in the food is very necessary and the milk should be cut down one-half. In order to insure fresh air, patients should be removed for an hour at least each day to another room. Cold air is good for most patients, but not down to forty degrees for young children. When the respirations are very high and the cough irritating, the canopy tent is of great service. In these conditions cold air would increase the spasm.

Spasmodic Bronchitis.—Dr. Walter Lester Carr said that in spasmodic bronchitis or bronchial irritation, steam is of service. It makes the secretion more abundant. Hot water bags to the feet will often so stimulate the patient as to make the secretion freer. The child's general condition must be watched and no overdistention of the abdomen allowed to occur. No syrups should be employed in the treatment of the affection.

THE JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Stated Meeting held February 15, 1904.

New Tube for Uterine Cultures.—Dr. Little exhibited this instrument, devised by himself, as a modification of the Döderlein tube. The latter is perfectly satisfactory when the lochia flow freely and there is no difference between the cervix and fundus as to bacterial contact. The tube is, however, somewhat difficult to work, the rubber portion often kinking in an annoying manner. In Dr. Little's modification the end of the piston is formed by an ordinary elastic band which is attached to a thread running down the tube and lies loose in the uterine cavity until drawn into the glass tube by the operator.

So-called Rheumatoid Diseases.—Dr. Goldthwaite read this paper. His attention to this class of cases had been called out by the swamping of his clinic by chronic cripples unloaded on him from the general practice of Boston. Study of the conditions had led him to a new classification of joint-affections based on pathological conditions: (1) Dry, hyperemic, relaxed or villous arthritis; a local condition characterized by congestion and folding of the joint membranes; occurs often in the knee and frequently accompanied by flatfoot. Treatment is by massage and prognosis is good. (2) "Rheumatoid" (better, atrophic) arthritis. A progressive condition characterized by swelling, followed by atrophy of joint and periarticular structures. (3) "Osteoarthritis" (better, hypertrophic arthritis); a very common form characterized by Heberden's nodes, thickening of cartilages and of bone; essential characteristic is hypertrophy; true anchylosis rare, but motion may be restricted. When spine is affected pressure pains are common. (4) Infectious arthritis. The absorption of any toxin may give a joint trouble; the absorption of the organisms themselves gives a specific arthritis. Rheumatism, since it is quite similar in its pathology to other infections, is probably due to unknown organisms. The pathology and treatment of all those forms are similar and they are subdivided into groups according to the infecting organism. In typhoid fever we may have the typhoid spine (due to absorption of the toxin) or a bone abscess (due to the organisms themselves). (5) Gout. Here there is a deposit of sodium urate and a constant bone change. The treatment of these conditions varies with the form. In the villous type treatment is expectant unless it is plain that removable villi are present. In the atrophic form local and general stimulating treatment modify the condition, perhaps even arrest it. In the hypertrophic form protection of the joint is indicated in the acute stage and later excision of the nodes if they are interfering with function. In the infectious form the same line of treatment is indicated as would be used in fighting a septicemia. Baths and depressing drugs should be avoided and salicylates are only indicated in the early stage, giving way later to stimulating drugs.

Dr. Painter discussed the pathology of these conditions. In the villous form there is a swelling of the capsule, a hypertrophy of the blood vessels, and an infiltration with red blood corpuscles. Little fluid is present. The cartilage shows a striation; it is thin and does not glisten normally. In the hypertrophic type there is no thickening of the capsule and the cartilage, though thickened, does not become striated or lose its glistening appearance. In the atrophic form the bone becomes smaller, the trabeculæ diminish in number and size and there is a deposit of fat in the intertrabecular tissue. In the infectious forms there is a general infiltration of all the elements more symmetrical than in the villous form. By MacRudden's new method the

metabolism has been estimated in these rheumatoid conditions and it has been found that the Ca and Mg in the feces of these patients is double that in normal feces and double the amount ingested.

Dr. McCrea said that the following classification of arthritis had been adopted at the Johns Hopkins Hospital: (1) Infectious cases with definite bacterial limits; (2) gout; (3) rheumatic fever—probably several organisms are concerned; (4) rheumatoid conditions, characterized by atrophy and hypertrophy which represent different manifestations of the same disease and are due to the toxins of many organisms. (5) Still's disease—infectious, accompanied by enlarged spleen. There is a definite series from this arthritis deformans of children up to the adult form. Dr. Finney said that he had removed lipoma arborescens from many joints but that he had done it in a half-hearted way. Since hearing Dr. Goldthwaite's paper, however, he would attack these cases with more confidence.

Dr. Emerson said that diminished Ca and Mg conological conditions seen in gonorrheal joints—from those cases with little fluid and no joint destruction to those with great destructive changes. Dr. Bloodgood said that this variation in the pathological picture bears a pretty close relation to the duration of the disease. In infectious arthritis opening and irrigating the joint may cause the process to recede and give a good functional result, but later scar tissue forms and poor function results. Early recognition is therefore important.

Dr. Emerson said that diminished Ca and Mg content in the feces had been observed in other conditions (diabetes) in which there was no bone change.

Dr. Goldthwaite, in closing the discussion, said that the atrophic and hypertrophic forms of arthritis, though different diseases, might coexist. They appear, however, at entirely different times of life. In gonorrheal joints he advised waiting until there were signs of infiltration of the capsule and then opening and irrigating. The ultimate results of surgical interference in rheumatoid cases depend on the particular case. In one of his patients, who had a mass of villi in his knee-joint like a bag of earth worms, the villi were removed and the function of the knee has been greatly improved. The cases can always be helped some.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Section on Clinical Medicine.

Stated Meeting, held February 19, 1904.

Laminectomy for an Intradural Spinal Tumor.—Dr. Cushing showed two cases. The first had been admitted to Dr. Osler's service at the Johns Hopkins Hospital complaining of disability of gait and pain in left arm—paroxysmal in character, not severe, increased by sneezing, etc. One year later sensory symptoms developed on the right side. The diagnoses suggested were tuberculosis of the bone reaching the cord, chronic cervical pachymeningitis, syringomyelia, tumor, and hematomyelia. Symptoms pointed to a lesion of the sixth or seventh cervical segment. Laminectomy was done, an intradural spinal tumor (fibrosarcoma) was found and removed. All symptoms disappeared immediately and the man is now quite well.

Left-sided Paralysis.—The second case had been shot in the forehead two years previously developing later left-sided paralysis and facial twitching with a difficulty of motor speech. Several operations were done and finally a bullet was removed. Soon after the patient developed epileptic convulsions without auræ or Jacksonian characteristics. The patient was also too easily amused and cried too easily—suggesting a frontal lobe lesion. An X-ray showed the bullet. A Wagner flap was turned down, five adhesions broken up, and the scar of the bullet tract and the bullet itself found and removed.

Pseudobulbar Paralysis.—Dr. Hirschberg read a paper on this subject. This condition was first described by Joffroy in 1872 and characterized by bulbar symptoms without demonstratable lesions in the bulbar nuclei. The symptom-complex may indeed be due to various pathological conditions. Gradual progression, electrical changes and tremors distinguish the Duchenne type of bulbar paralysis from the false type; atrophy, distinguishes polioencephalitis; recovery, distinguishes myasthenia gravis. Pseudobulbar paralysis occurs after two apoplectic attacks, shows normal electrical reactions and more or less marked mental changes(aphasia, involuntary laughing and crying, etc.). There is often a histry of lues. Arteriosclerosis of the basilar vessels and foci in both hemispheres have been found pathologically. Dr. Hirschberg's case complained of poor locomotion and gave a leutic and marked alcoholic history. Two attacks of apoplexy had occurred and after the last both legs and arms had been paralyzed, memory had been poor and some delusions present. Voice was weak and hoarse, palate reflex gone on left side. No improvement had occurred under specific treatment.

Dr. Thomas said that this condition was not an entity at all but a symptom of varied pathological conditions and the name "Pseudobulbar Paralysis" was a poor one. One apoplectic stroke leaves no palsy of these muscles, because they are bilaterally represented; but after a stroke affecting each side the condition occurs.

Multiple Pelvic Fracture, with Rupture of Urethra and Bladder.—Dr. Harrison reported this case. The man had been admitted to the hospital badly shocked and suffering with great pain, paralysis of the legs, desire but inability to urinate. Catheter obtained only blood. Operation revealed multiple fracture of the pelvis, and extraperitoneal rupture of the bladder and a rupture of the urethra—the prostatic portion having been stripped out of the prostate. Tube and gauze drainage were inserted suprapubically and peritoneally; no suture of bladder or urethra was done. Recovery was good. Patient now passes urine six or eight times during the day, sometimes not getting up at all at night. Passes a No. 26 sound with ease and there is no bleeding. He has no erections (injury to pudic nerve ?) but desire is present and ejaculation occurs on masturbation.

BOOK REVIEWS.

Infectious Diseases, their Etiology, Diagnosis and Treatment. By G. H. Roger, Professor Extraordinary in the Faculty of Medicine of Paris. Translated by M. S. Gabriel, M.D. Lea Brothers & Co., New York and Philadelphia.

The time has seemed ripe when the vast number of researches on the infectious diseases might be brought into a comprehensive synthetic whole, and Roger has made an attempt to do so and has succeeded most admirably.

The work is a truly philosophical one that is both stimulating and practical. General laws rather than small details are considered and the subject of microbic growth, poisons and the body's defensive agencies are set forth in a new light that compels thought and inspires new ideas.

The work is a large one, over twenty-four chapters occupying eight hundred pages. General Considerations, Characters of Pathogenic Bacteria, Etiology of Infections, Pathology of Infections, Microbic Associa-

tions, Defense and Reactions of the Organism—are the titles of the earlier portions of the volume. Then follow considerations of some of the effects. Suppuration, Gangrene, Septicemias, Nodular Infections, Cellular Degenerations and Fever being discussed in these chapters.

In four further chapters the influence of Infections on the various parts of the body is discussed from entirely modern viewpoints and the evolutions and consequences of infection further treated.

From the therapeutic side the author takes up the study of the Mechanisms of Immunity, and in three final chapters deals with the Therapeutics of Infectious Diseases—their Hygiene and Prophylaxis.

Truly this is a desirable acquisition to the English-speaking student—made most attractive by the publishers' best art.

Atlas of the External Diseases of the Eye, including a Brief Treatise on the Pathology and Treatment. By Prof. Dr. O. Haab. Second Edition, Revised. Edited by G. E. de Schweinitz, A.M., M.D., Professor of Ophthalmology in the University of Pennsylvania, etc. With 98 colored lithographic illustrations on 48 plates. W. B. Saunders, New York, Philadelphia and London.

The second edition of this book can only elicit the unqualified commendation given on its first appearance. It is a remarkable achievement, both as a work of art and as a scientific production. The thoroughly scholarly text is illuminated by the illustrations as is seldom the case. A certain amount of new matter, together with eight colored plates, have been added to this edition. The book, with its plates, is not only to the credit of the author, but is truly an achievement with which the publisher may well be satisfied.

Diseases of the Eye. By L. Webster Fox, A.M., M.D., Professor of Ophthalmology in the Medico-Chirurgical College of Philadelphia. With five colored plates, and 296 illustrations in the text. D. Appleton & Co., New York.

The author offers this treatise as the outgrowth of his experience as a lecturer during the last ten years. He states that it is his object not to supply a mere ephemeral sketch of existing information on ophthalmology, but to provide a digested summary of the known facts. The publisher's work has been admirably done. Many of the illustrations are familiar as having been borrowed, doubtless, by the courtesy of the publisher from better known books, without recognition, it may be stated. As a statement of personal opinion with regard to many mooted points the book has a certain interest, but it can hardly be called well-digested when seventeen operations are mentioned for the relief of ptosis while toxic amblyopia is dismissed with a few sentences, and the relation of ocular disorders to constitutional diseases and disorders of the nervous system occupies two pages. There are many statements which might be considered inaccurate or misleading, which it is not necessary to specify. But in a certain sense the book will undoubtedly appeal to those for whom it is intended, because it contains allusions to many of the most recent procedures. In this sense it is certainly up to date.

Practical Gynecology. A comprehensive Text-Book for Students and Physicians. By E. E. Montgomery, M.D., LL.D., Professor of Gynecology, Jefferson Medical College, etc. Second Revised Edition. P. Blakiston's Son & Co., Philadelphia.

It is probable that more books have appeared in the last few years on gynecology than on any other similarly restricted field of medicine and yet the editions of each keep multiplying with a regularity that must at least be gratifying to their authors and publishers. The popularity of the present volume is easy to understand, however, for it is certainly one of the most attractive and readable in use. The work of revision has produced notable changes in arrangement, and in rewriting and keeping pace with more recent operative procedures, seventy pages have been added. In the section on the operative treatment of retroversion the author describes many of the newer operations and also a method of performing ventral suspension differing from his former practice.

The illustrations form a conspicuous feature of the book and many new ones have been added to this edition. Nearly all are original and their uniformity of execution is most pleasing. The numerous drawings of microscopic sections are particularly well done and serve to show how much superior for teaching purposes good drawings are to the poorly reproduced photomicrographs which have lately become the fashion in illustrating.

All in all, this is a most satisfactory work, modern in teaching and practical in application, with the subject-matter well arranged and attractively presented.

A Treatise on Orthopedic Surgery. By Royal Whitman, M.D., Instructor in Orthopedic Surgery in the College of Physicians and Surgeons of Columbia University, New York, etc. Second Edition. Lea Brothers & Co., Philadelphia and New York.

This is in every way a most valuable and agreeable book in which the soundness of the author's views as to pathology and treatment is equaled only by the wealth and appropriateness of the illustrations. Most of these are from photographs and have been prepared with a skill and discrimination that leave little to be desired.

In this edition the work has been revised and some new matter and illustrations added, though no important changes seem to have been required.

Perhaps in no other department of medical writing is a profusion of illustrations so necessary as in this, where countless forms of apparatus and their methods of application have to be described, and too much cannot be said in praise of the figures in this book, which really illustrate and show unusual thoughtfulness and care in their selection, preparation and execution. All the newer procedures, such as the Lorenz method of reduction for congenital dislocation of the femur are clearly described and figured, while the author's eminence in his specialty renders the book not only complete and up-to-date, but also authoritative.

The Four Epochs of Woman's Life. Maidenhood, Marriage, Maternity, Menopause. By Anna M. Galbraith, M.D. With an Introductory Note by John H. Musser, M.D. W. B. Saunders & Company, Philadelphia, New York and London.

Dr. Musser's introduction runs thus: "It has been well said that the bulwarks of a nation are the mothers. Any contribution to the physical, and hence the mental, perfection of woman should be welcomed alike by her own sex, by the thoughtful citizen, by the political economist, and by the hygienist. Observation of the truths, expressed in a modest, pleasing, and conclusive manner, in the essay of Dr. Galbraith, contribute to this end. These truths should be known by every woman, and I gladly commend the essay to their thoughtful consideration."

This should of itself be an excellent commendation of the book, and physicians will find it an excellent instrument for giving important information easily, thoroughly and without any possibility of offense.

ORIGINAL ARTICLES.

THE INDIVIDUAL EQUATION OF THE PATIENT IN SURGICAL OPERATIONS.*

BY W. L. ESTES, M.D.,
OF BETHLEHEM, PA.

ASEPTIC methods have so minimized the immediate danger of surgical procedures, and modern surgical technic has given the surgeon such facility in operating, that nowadays operations are undertaken lightly and performed with comparative safety, and with very little anxiety as to the recovery of the patient from the operation itself, in the majority of cases. Occasionally it happens, however, that a patient dies upon whom an operation has been done of a kind which the surgeon has performed for others many times without any serious result, and after what seems a perfect carrying out of a thoroughly well planned and an ideal operation; also without any manifest contraindication on the part of the patient.

I am sure every surgeon who does much operative work has had occasion to ask himself in a given case, why did that patient die when so many other patients have recovered who seemed in no better condition and who in many instances were actually less able to stand the operation than he was? I believe the answer to this question is, "It was on account of the individual equation of the patient." The fact that there is an average result among a large number of individuals operated on naturally suggests that there is an average vital personality. There are many exceptions to this rule, however. I think surgeons ought carefully to consider these possible exceptions in undertaking any operation of expediency and bear them in mind in prognosing.

It is my purpose to call attention to a few conditions which may affect the reaction of an individual to a traumatism and which may vitally affect the result of an operation. The first of these conditions is heredity. Barring the exanthemata, in which class I may for the instance place syphilis, it is probable that no disease is actually transmitted as such, from parent to child. It has been abundantly proved that individual proclivities both of physique and disposition are transmitted to children from parents (there are probably just as many instances of atavism in the matter of physical qualities as there are in physical appearances and mental qualities of an individual). There is further much evidence to show that there is a chemical individuality which may be transmitted as a family trait. The well-known instances of hemophilia belonging to certain families for a number of generations would indicate this. It is of great importance then for the surgeon to find out the family history of his patient.

The manifestations of heredity in the second generation of syphilitic, of tuberculous and of cancerous families are so nearly related that it seems in some instances they are interchangeable. That is to say, an individual whose parents have had syphilis seems as much disposed to cancer as one whose parents have had cancer. Such an inheritance also renders the child as liable to tuberculosis as if he inherited the tendency directly. I am not able authoritatively to speak in the converse, that is, I have not sufficient evidence to show that the tuberculous and cancerous inheritance also disposes toward syphilis. I believe, however, it would only be fair to extend the parity of reasoning thus far. A cancerous inheritance undoubtedly disposes toward tuberculosis, and a tuberculous inheritance disposes toward cancer. This all means that the physiologico-chemical resistance of the cells and tissues is so reduced by an inheritance of a diathesis that the individual is particularly susceptible to microbic inoculations. Incidentally this may be used as another argument for the microbic origin of cancer.

All surgeons know that individuals react very differently to sepsis. Some are overcome at once, while others bear an exceedingly virulent invasion with comparative safety, and others still occupy a middle ground with reference to vicious micro-organisms. Some individuals after operations recover from most exaggerated conditions of septic peritonitis brought on by fulminating and gangrenous appendicitis or salpingitis, while others, apparently equally strong in every way, succumb to a very mild form of sepsis, even after the most careful and painstaking operation and unremitting care and skilful after-treatment. It is true that all apparently mild conditions of sepsis from appendicitis are really far from being such, as they may possess the potential features of a most virulent and fatal inoculation. On account of a pylephlebitis of the distal branches of the portal vein, thrombosis of these branches may and frequently does exist in cases of abdominal sepsis, subsequent detachment of the emboli laden with streptococci and staphylococci and their lodgment in the liver or in some nearer small vein may serve to determine many of the so-called "inexplicable deaths" which follow "ideal appendectomy" (Dr. A. G. Gerster, in a paper read before the last meeting of the American Surgical Association, very forcibly demonstrated this fact), but why do some cases escape these several manifestations of advanced sepsis, while others with as nearly as human foresight and experience can procure the same careful technic and

*The Address in Surgery delivered before the Pennsylvania State Medical Society.

management, die on account of this blood poisoning? I think but one answer may be given to this. Namely, individuals inherit or acquire varying powers of resistance. Some persons undoubtedly have inherited comparative immunity on account of the superior qualities of the antitoxins and cytolysins of their blood and tissues. That environment and habits also have to do with this is no doubt true, and I will mention this point under another head presently. As Darwin has shown, however, it requires many generations to change materially the outer form and characteristics of an animal by environment. We may fairly conclude that the quality of the cells *does* improve with the general improvement of the physique of the individual, but there is abundant evidence to show that the apparently most robust individual is not always the most resistant to septic conditions. If there were time I might cite numerous instances of this fact, but I am sure, it is thoroughly familiar to you all.

To sum up this head in a postulate, I would say:

1. Dyscrasias may be transmitted by inheritance and weaken the resistance of animal cells to toxins; individuals who have such an inheritance are particularly liable to microbic inoculations, and do not develop antitoxins and cytolysins of sufficient potency to overcome infections. Such individuals are apt to die from very mild forms of sepsis after operations.

Another circumstance which materially affects the results of operation is the:

2. *Environment and Habits of the Patient.*—It is not necessary to argue this point from any profound scientific basis. It is now commonly conceded that human beings, in common with all animals, are markedly modified by their continued surroundings and their modes of living. In the ultimate scientific conclusions this belongs properly to heredity. I wish rather to call attention to some ordinary observations which bear on this matter.

It will be conceded at once that individuals who have habitually and for long periods been subject to very bad sanitary and unhygienic conditions do not bear operations well. My observations and experience have convinced me, however, that the bad conditions of this kind are not confined to city and town life. The advantage of free outdoor life with pure air during the daytime in rural life is, in many instances, more than overbalanced by the lack of ventilation and crowding in the sleeping apartments at night, and the very common habit of eating poor and improperly cooked food, which is prevalent among farmers. Farmers eat a great deal of pork, salt and dried meats, and canned vegetables. They have the advantage, it is true, of fresh fruits in their seasons, but they use these fruits without discretion, usually immoderately while they last, and they very rarely ever have their meals properly cooked. There is no class of people, in my experience, so given to indigestion and the varying concomitant intestinal disturbances as farmers are. The children are commonly poorly nourished and only in early adult life do they seem near the proper standard of development and nourishment. Farmers are so poorly nourished and their digestive organs are usually in such wretched condition that they are not good subjects for severe operations, and they are very liable to septic inoculation.

City people, besides being better fed as to quality of food, have their meals better prepared as a rule, except in the very poorest classes, and they have, on account of daily necessity, acquired a certain degree of immunity to sepsis. Their antitoxins and cytolysins are continually stimulated and are in constant use. They are, therefore, not so liable to septic developments as farmers. Except the very poorest people who live in the congested tenement districts, who are subjected to foul air and surroundings, and who live on scanty and poor food year in and year out, I think city and town-reared people stand operations better than the ordinary farmers.

Besides the environment, *the habits of the individual* have much to do in determining the result of an operation. The excessive indulgence of any appetite lowers the resistance of the whole system to traumas. I have found especially that the excessive indulgence in beer markedly increases the tendency to phlegmonous inflammations. Beer drinkers furnish most fertile soils for streptococcal development. They are also most unfavorable subjects for general anesthesia.

Whisky drinkers are not only difficult to anesthetize but they are very subject to postoperative nephritis, pneumonia and delirium tremens and on account of frequent atheroma they bleed more and they are more apt to die from so-called "exhaustion" after operation.

Vegetarians, or persons who live chiefly on vegetables, do not stand the loss of blood well, and they are peculiarly liable to die from acute anemias. They also react very poorly to saline infusions for the restoration or the substitution of the circulation of the blood in cases of exhaustion after severe hemorrhage. On the other hand meat eaters, the full-blooded and plethoric individuals, do not as a rule stand general anesthetics well. It requires much skill to bring them under the anesthetic and constant and very skilful care to prevent asphyxiation when fully under, especially when ether is used. If the heart be absolutely sound chloroform should be the anesthetic of election in these cases.

3. *Disposition of the Patient.*—Unquestionably, I think, a bright, cheery, sanguine and courageous disposition tends markedly to favorably influence the result of any major operation. I always feel handicapped in operating on a despondent and excessively anxious subject. Nervous energy counts tremendously in the reaction, resistance and tenacity of an individual after an operation. This has more to do with the outcome of a severe operation than mere physical fitness. I hesitate long and undertake with many misgiv-

ings a serious operation on a person who "knows he will die from the operation." Such individuals do recover many times undoubtedly, but if aught goes seriously wrong their mental laxity and lack of nervous tone almost surely bring them to the grave.

4. *Age.*—The extremes of age increase markedly the bad prognosis of an operation. Very young children and very old people do not bear anesthetics well, nor can they stand the loss of blood. Such individuals are apt to die after long operations, and operations done for very vascular tumors, or in regions where complete hemostasis is impracticable. Of 85 deaths after operations which have occurred in St. Luke's Hospital the last ten years, 7 were under five years of age; 10 were five to twenty years; 23 were twenty to forty years; 30 were forty to sixty years, and 15 were over sixty years of age. These I presume are average statistics, and while the number is too small to make any valuable generalization, they indicate that, barring the extremes, the exact period of life itself when an operation is endured does not make any material difference in the result.

5. *Sex.*—This seems to have no marked influence in the result of an operation, provided the physical condition is good.* I think my experience has shown, however, that women bear operations for septic conditions of the peritoneal cavity better than men do. Probably the superior vascularity of the pelvic region in women, which is most frequently the seat of septic inflammations and accumulations, will account for this. Another fact may also influence this result, namely, that men use the diaphragm much more than women do in breathing. The action of the diaphragm tends to draw, by intermittent pressure, and relaxation, the lymph current upward. In men, therefore, septic products are much more apt to ascend to the subphrenic and supraphrenic lymph nodes, a lodgment which is well known to be especially apt to cause fatal results.

6. *Nationality of the Patient.*—This in my experience makes little difference in the result of operations. I have observed, however, that the lower classes of Slavs and Italians, such as are met with in this part of the country, are apt to be very emotional, and are very intolerant of pain, and are very difficult to restrain after serious operations. Crying and extreme restlessness must of course make great difference after some operations, and on this account these two classes of patients are not desirable subjects for major operations.

7. *Physical Condition of the Patient.*—The most important point for the surgeon to find out, and accurately to gauge, *is the physical condition of the patient at the time of the operation.* So-called "laboratory methods" have greatly broadened the scope of the former routine of physical examinations. The accuracy of the determinations of the character of excretions, of the blood and of most of the secretions, nowadays in the laboratories give us certain data which are of immense value. I believe, however, surgeons are inclined to depend too much upon laboratory investigations and neglect the old methods of bedside examinations, or at least they relegate them to secondary importance. I believe that in no other field of medicine do the methods of Zadic so constantly apply, and are of such constant value as in surgery. In some instances the findings of a personal physical examination should supersede or qualify the determination of a laboratory conclusion. For instance, laboratory investigations tell us that an operation performed on a patient whose hemoglobin is below 40 per cent. is usually fatal. Yet I am sure we have all had uninterrupted recoveries and no serious result after many operations done on patients whose hemoglobin was below 40 per cent. It is true most individuals who have a cachexia and, on account of this, slow poisoning and undermining of their health and gradual deterioration of their blood and have less than 50 per cent. hemoglobin, are not safe subjects for operations. It is a different matter, however, if this lowering of the hemoglobin comes from a hemorrhage or from a series of hemorrhages.

Again, it is conceded that albumin and granular casts in the urine indicate that the patient who excretes such urine is a very unsafe subject for anesthesia, especially ether anesthesia, and markedly increases the danger of any operative procedure. Large ovarian and uterine tumors are apt to produce, on account of pressure and mechanical interference with the blood supply and circulation in the pancreas, liver and kidney (chiefly the portal system) just such indications in the urine; the affected organs are relieved and the vitiated renal excretion is entirely remedied by the removal of the tumor, and the operation does not prove extrahazardous in these cases. I might multiply instances of this kind.

I wish to urge the great importance of a careful and thorough physical examination of every patient by the surgeon himself, or by some one qualified to make careful physical examinations. This should be done before even minor operations of expediency. Subjective symptoms may sometimes clearly indicate the seat of a lesion requiring surgical interference, in other cases it requires a careful systematic physical examination to find the disease. For instance, rectal carcinoma is frequently attended by very decided gastric symptoms. I have observed this in a number of cases, notably in one case the gastric symptoms were so pronounced that for months the patient was treated by some of the best internists for gastric disease. After the carcinoma was found and removed the stomach symptoms disappeared entirely.

It is a matter of serious importance that scarcely one medical school in the United States teaches its students to use their *eyes* in examining a patient. Students are laboriously indoctrinated

* My statistics show: Taking out 15 deaths after operations done for bad crushes, which were practically all men, 37 males and 33 females died out of 85 fatal cases.

into the importance of carefully cultivating their senses of touch and hearing, and are taught thus how to discriminate between normal and abnormal protuberances and sounds of the body, but we scarcely can find a student who thinks of first carefully *inspecting* the surface of his patient's body or his extremities in order to see and thus note any abnormalities, and to know how to discriminate between the normal and abnormal contour and color, or tension of the body. Many instances have come under my observation where this lack of training has led to serious errors in diagnosis. Unquestionably, I think both personal, clinical and laboratory examinations and investigations should be made, whenever it is possible to have them done before all serious operations.

Organic diseases of any of the viscera greatly modify the prognosis of operations. Dr. J. R. Bradford* calls attention to certain so-called "latent diseases," that is to say, these diseases are of such a kind that they might exist in a given case without any special evidence of their presence, and unless one makes a careful painstaking examination they might not be recognized. Operations done for some other cause might be particularly hazardous on account of these latent diseases. The diseases mentioned by Dr. Bradford are: (1) Nephritis, (2) diabetes mellitus, (3) typhoid fever, (4) rheumatism, (5) latent cerebral abscess from middle-ear disease, (6) pleural effusions, (7) gastric ulcer, (8) malignant disease of the stomach, (9) gallstones, (10) the rare condition of a high degree of atrophic cirrhosis of the liver in children. This condition may produce symptoms of acute peritonitis. All these diseases may be excited to active conditions from the latent state by any operative procedure and may prove disastrous to the patient.

General arterial atheroma or endarteritis deformans also contributes markedly to the danger of an operation. When this condition is accompanied by an intermittent heart action, no matter how well the patient may otherwise seem to be, the prognosis after any serious operation is very grave; the coronary arteries are involved and the heart is fatty.

As was suggested before, patients who are already in serious septic states, especially those who have septic peritonitis, are very bad subjects for operations. The reason is, in these septic conditions it is frequently impossible to get rid of all the septic matter. There is frequently pylephlebitis of the branches of the portal vein, or infection of the posterior lymph nodes of the peritoneum. The most thorough washing out and drainage will not relieve the patient in these cases. However the all important point *is thorough drainage*, after thorough removal of the septic products and thorough cleansing. The posterior route should be used for men, the vaginal for women. Fowler's position is good for women, for men lumbar drainage is better. Of the 85 deaths after operations which I have had in the last ten years, 40 of the patients were already septic.

Patients who are seriously affected by malaria are also bad subjects for operation, so are also leucocythemic patients.

It is the duty of the surgeon to find out the existence of any organic disease, and reasoning from what he knows of its nature and tendency he should apply this in estimating the effect in his proposed operation.

8. *Extent and Locale of the Operation.*—Aseptic surgery and the technic of thorough hemostasis have robbed extensive operations of much of their danger. There are no "noli me tangere" regions in the human body now. Still there are two regions which seem to be especially unfavorable for extensive operations. I refer to (1) the base of the brain and (2) the thoracic cavity. With great care even these two regions may be invaded without serious results. For instance, I have recently had two very extensive crushes of the cranium which involved the base on both sides as well as the vault, and which required exploration of the base of the brain on both sides, make rapid recoveries even though there were great hemorrhage and injury to the cerebrum. I have also removed a large segment of the thickness of the thoracic cavity in an operation for a secondary scirrhus and sewed the lung to the opening in the walls of the thorax, and finally by using the external surface of the lung to block up this opening have succeeded not only in saving the life of a cachectic woman but also secured an excellent functional result for both lung and thorax. Notwithstanding these and many other good results, notably the closing of many wounds of the heart, which other surgeons have had in these regions, the fact remains that these two are perhaps the least favorable of all the regions of the body to invade. One must always bear this fact in mind in estimating the chances of any case which requires operation in these regions. The scope of this paper will not permit me to go into the reasons for the bad prognosis of operations on the base of the brain and in the thoracic cavity. I must refer my hearers to modern textbooks for further discussion of this subject.

Thus I have tried to show that inheritance, environment and habits, disposition of the patient, age, sex, nativity, physical condition of the patient at the time of operation, the extent and locale of the operation—all have something to do in determining the personal equation of the patient about to be operated on. I reiterate that it is the surgeon's duty conscientiously to endeavor to find all the data which will enable him to determine the importance of all these points with reference to any individual upon whom he intends to operate. This means he must take a careful history of the patient including his family history as far as it may be definitely obtained. Also he must make a careful and thorough physical examination, and call to his aid laboratory investigations. With an experienced and careful sur-

* Lancet, April 4, 1903.

geon I am disposed to lay the greater importance on the personal physical examination, and should rather trust to this than to laboratory findings to determine the possible danger of any proposed operation, taking for granted, however, that an examination of the urine shall be one of the examinations included in my term personal physical examination.

Reflection on this subject and these facts which so critically influence our operations suggests that more difficult than determining when to operate is to know *when not to operate,* and this last is, to the patient, in many instances far more important. Our age is inoculated and thoroughly intoxicated with the furor for operations. I think it is time for thoughtful educated surgeons to study more the prevention of operations than new operative procedures.

Preventive surgery is just as possible and important as preventive medicine. Let us continue to try to learn the cause of the various surgical conditions, and also try to remove these causes and so prevent the disease. As Sir W. H. Bennett has properly said, the majority of surgical operations come from the three most prevalent diseases—(1) cancer, (2) tuberculosis, (3) syphilis. If surgeons would try faithfully to prevent these, fewer operations would be necessary.

We do not yet know the actual agent which causes cancer. We do know, however, that constant irritation of a part, especially where mucous and cutaneous surfaces are in juxtaposition, will produce epithelial cancers. Forbidding the use of a short stem pipe, or *any* smoking, or the filing of the sharp edge of a tooth may prevent epithelioma of the mouth and lips. Attention to little ulcers of the anus, the early amputation of a degenerated uterine cervix, which has previously been neglected after it has been lacerated, may prevent cancers of the rectum and uterus.

Further, it is generally conceded by pathologists as well as surgeons that even after a lesion has started there is a period which may be called the precancerous period, during which a tumor which may subsequently be most malignant has the qualities of a benign tumor, and may be removed with assurance that it will not recur. It is of the greatest importance that every tumor shall be removed as soon as it develops. People generally are not thoroughly impressed with the tremendous importance of this fact. Surgeons should endeavor to educate the people to thorough appreciation of this. By educating the people tuberculosis is finally regarded as a disease which may be prevented, and people have been taught and are being taught what measures to take to prevent this dread disease. Its half brother, the far more dreadful cancer, may also be prevented, at least in some instances. Surgeons first should teach family physicians, and they in turn their families, how to prevent and to stop the progress of cancer.

Temporizing in surgery will not do. People should be taught that when they have any tumor or lesion of any kind which requires removal or operative interference, it is of vital importance to have it done at once. Physicians frequently do not believe this themselves, else surgeons would have far less trouble with cases which have "gone too far."

In conclusion, I beg to appropriate the words of Sir W. H. Bennett:* "In the meantime taking things as they are, it is well that we should beware lest a single predominant factor should be allowed to lead to our regarding, through a small tube only, a subject the horizon of which is absolutely unlimited. It has been said that the basis of surgery is handicraft, and this, in a sense, is true; but surely it is truth only half told, for apart from the issues to which I have referred there is lying behind a far greater thing, the knowledge of when to apply that craftmanship of which every one who now aspires to the practice of surgery should make himself a master. Nothing that has happened in the improvements connected with the practice of our art justifies, so far as I know, the modification by one iota of the edict of the great surgeon, who before advancing science had robbed operations of most of their horror said, 'The all important thing is not the skill with which you use the knife, but the judgment with which you discern whether its employment is necessary or not.'"

VALVULAR DISEASE OF THE HEART AND ITS TREATMENT. CASE OF MITRAL OBSTRUCTION AND INSUFFICIENCY WITH TRICUSPID REGURGITATION AND PULSATING LIVER.†

BY STEPHEN SMITH BURT, A.M., M.D.,
OF NEW YORK;
PROFESSOR OF MEDICINE, NEW YORK POST-GRADUATE MEDICAL SCHOOL; ATTENDING PHYSICIAN, NEW YORK POST-GRADUATE HOSPITAL.

To properly care for a patient with valvular disease of the heart one must be aware of the difference between established and ruptured compensation, and also capable of making the clinical distinction. The ability to decide whether hypertrophy or dilatation prevails in a given case presupposes a practical knowledge of physical exploration. Without doubt many persons in whom valvular defects of the heart have been revealed are injured by indiscriminate treatment.

For example, I was called in consultation to see a young girl who had mitral regurgitation. There was no evidence that the consequent dilatation of the heart was not well balanced by the hypertrophy. However, she was nauseated and almost pulseless at the wrists, and the heart was beating and throbbing tumultuously. It appeared that she had been getting large doses of digitalis every four hours for several days for no other reason than that a bruit had been discovered. Here the remedy lay in the stopping of the medicine. Cardiac valves once injured by disease must of

* Lancet, May 23, 1903.

† Read before the Section on Medicine, at the New York Academy of Medicine, Jan. 19, 1904.

necessity remain more or less defective, but within certain limits nature repairs the damage by increasing the muscular power of the heart. Resulting dilatation of the cavities is balanced by hypertrophy of their walls, and it is not until this hypertrophy is overcome by secondary dilatation that treatment is indicated.

The outlook for a patient whose valves are affected depends upon the location as well as the character of the affection. If it be a stationary lesion, that is to say, merely the scar of an old inflammation, other things being propitious, the prospects are favorable. But if there is a progressing sclerosis, the duration of the compensatory adjustment is uncertain and likewise the prediction. In aortic patency without stenosis, though sudden death is always a possibility, the patient may continue to live indefinitely. An associated contraction of this orifice is a saving factor in the prognosis. Obstruction alone is very much less serious than regurgitation. Mitral stenosis and mitral insufficiency are about equal in their eventualities. Neither commonly results in sudden death yet the end begins, however gradual and deferred it may be, with the rupture of compensation. We can say what may happen in a particular instance of valvular disease, but to say what will happen is a different undertaking. A man in whom a mitral insufficiency was noted by me during a routine examination more than twelve years since is still in excellent condition. Sixteen years ago a young man consulted me about an aortic insufficiency, not that he was inconvenienced thereby but because my advice was recommended. Thus far there has been no serious break in compensation. One patient with a mitral insufficiency that was due to a lesion which was stationary and in compensation has been under my observation for twenty-two years, and another likewise conditioned, for twenty-three, and neither in the meantime has suffered therefrom anything more than occasional breathlessness. There was a dentist who came to consult me, in his sixty-third year, on the first appearance of a broken compensation for a double aortic lesion and a mitral insufficiency. Forty years previously, he had been examined by three physicians, at different times, who each made the diagnosis of a valvular disease, and informed him that he could not live more than two or three years at the utmost. With ill-concealed gusto, commenting upon their powers of prognosis, he told me that he had outlived them all many years. Recently there was a young woman, just up from childbirth, in my service at the Hospital suffering from pleurisy and pneumonia, who also had a mitral stenosis of old standing, generally a serious complication, yet, owing to her youth, good constitution and an unbroken compensation, she recovered. Valvular disease that has lasted for long in persons advanced beyond early middle life is apt to be associated with degenerative changes that make an attack of pneumonia or the taking of an anesthetic extremely hazardous. On the other hand, a valvular disease previous to this period, in good compensation, is not necessarily fatal in pneumonia or dangerous in anesthesia. Lastly, there is an instance known to me of a man who lived with a valvular disease of some nature from the time he was eight years old until he was ninety-four, and from the results of which disease, after this remarkable record, he succumbed.

It is my desire when feasible, which is by no means always, in advising a patient with valvular disease frankly to explain the condition of affairs, without provoking undue apprehension, and thereby to forestall a fortuitous rupture of compensation. This would seem to be our duty if we expect to shield him from what is certainly at all times impending. He then can act intelligently, and if he fails to observe our instructions, he alone will be answerable. Excesses of various kinds are prone to lead either to sudden death or to a break that is equally fatal eventually. For instance, a young man with mitral stenosis, but otherwise in excellent condition, who had reason to look forward to many years of comparative activity, through excessive exertion as an athlete brought about a disturbed compensation. After restoring things to their proper relations, by suitable treatment, my earnest advice was that he should forego all violent exercise in future, nevertheless he persisted, despite my warnings, in the practice of wrestling, and in less than two years broke down and died. There is no reason why a vocation or an avocation should be abandoned unless inordinate physical or mental strain is involved, by a person who happens to have a valvular defect for which there is adequate compensation.

Early hours for retiring at night, and sleeping in well-ventilated apartments are advisable. The life of a ready normal sleeper and a believer in fresh air is generally prolonged. Nourishing food in small quantities, eliminating whatever tends to produce flatulence, should be taken with regularity. Habitual light eating rather than any special form of diet best insures against the ills which we acquire but flatter ourselves are inherited. Mild wines may be drunk at meals if custom and taste so demand, but strong alcohol as a beverage at all times should be eschewed. The use of tobacco, except in great moderation, is harmful in cardiac disease. Daily bathing, preferably in warm water, is necessary to keep the skin active, particularly for those whose lives are sedentary. Whether the shock of the cold bath is injurious or not, like many other things, after all resolves itself into the personal equation. Some close observers are aware of a secondary reaction an hour or two after a matutinal cold plunge, even when a warm glow follows the immediate emersion, that amounts to a depressing chilliness. Very hot baths, including the Russian and the Turkish variety, are exceedingly dangerous. Surf bathing and swimming, unless carefully indulged in, are liable to overtax the heart and cause prostration. In regard to the clothing, it should be suitably warm but not cumbersome, and suffi-

ciently porous in texture to insure ventilation. Linen mesh underwear and enough woolen in the shape of other garments for warmth or comfort are in my opinion the ideal combination. Still, woolen drawers may have to be worn by sensitive persons in cold weather owing to the fewer outer coverings of the lower extremities. There should be a frequent change of underclothing, particularly of the stockings. To condemn a patient to inactivity simply because there is a valvular obstruction or leakage though well compensated is the height of mismanagement. Regular moderate outdoor exercise is essential to his bodily welfare. It facilitates the removal of the products of disintegration, and supplies new life to the cells and tissues, including those of the organ whose integrity we are especially desirous of maintaining. Let it be understood, however, that there shall be no violent muscular exertion. No boat racing, football, baseball, wrestling, running, jumping, or any severe athletic contests or heavy gymnastics. Walking, golf, riding, rowing, fishing, hunting, and many games and outdoor occupations that are not too strenuous can be safely permitted. Systematic walking in the open air, preferably upon a level, while practising deep breathing, though possibly not interesting, is the safest of exercises and one of the most beneficial. High altitudes are not well endured and may be dangerous. Worry and excitement are to be avoided as much as possible. Indeed, moderation in everything that pertains to daily life is the keynote of the entire situation. These precautions may be neglected by the subject of a valvular disease with impunity for a certain period, but such negligence is sure to result, sooner or later, in sudden death, or a more gradual rupture of compensation, which last is the beginning of the end, however delayed by judicious treatment.

Although undue shortness of breath is one of the early symptoms of a failing compensation, nearly every patient with a defect of the mitral valve suffers on extra exertion a certain amount of breathlessness. This is without serious significance. It is simply a passing disturbance of the balance in the circulation which is slightly in excess of what occurs under the same circumstances to the average healthy individual. When the compensation is really ruptured, provided death does not follow immediately, there will be evidences of dilatation of the heart, shortness of breath, dyspnea, possibly cyanosis, and cardiac palpitation. The action of the heart becomes irregular, there is usually dropsy that first appears about the ankles, and which eventually becomes general. Passive effusions are prone to collect in the pleuræ and the pericardium. In regard to an irregular pulse in mitral lesions, in which every few beats are full and strong, despite the weakness of those intervening, there need be no particular alarm. Here the few recurring strong beats are an evidence that the heart is really not weak, whatever the cause of the irregularity. Irregularity of the pulse in aortic disease is commonly a serious manifestation. Bronchial and intestinal catarrh are among the very early symptoms of a loss of balance between the arterial and venous circulation. When the ordinary remedies fail in these troubles a little digitalis added to the prescription will sometimes result most favorably. Likewise in regard to periodical uterine hemorrhage. There was a patient of mine with mitral stenosis who was greatly exhausted each month by menorrhagia. This was materially controlled, after the difficulty had been analyzed, by full doses of the infusion of digitalis just prior to and during menstruation.

Whatever doubt there may be about the advisability of letting the patient know that he has a valvular defect, during its period of relative latency, even when all fears are carefully explained away by showing its comparative harmlessness, there seems to be but one course to pursue where hypertrophy of the heart has been overcome by dilatation. To be forewarned is to be forearmed in medical matters, as well as elsewhere, against an end that is threatening. In mitral disease the slight beefy redness of the lips that can be seen if the patient is closely observed after even moderate exercise, and the trifling shortness of breath which occurs, safely can be disregarded if on resting they quickly disappear.

When a ruptured compensation becomes pronounced, and in fact through all grades of disturbed equilibrium, rest is of paramount importance. It is not infrequently all that is required for rehabilitation. To me there is little reason in the attempt to restore a cardiac muscle that has lost its elasticity by subjecting it to further stretching by the strain of such performances for example as mountain climbing. Massage in properly selected cases is often serviceable. And also as a sequence to the all-important period of rest some of the so-called resistance-movements. In passive exercise there are, when the time is wisely chosen, many features that are desirable as well as in active exercise. On the whole, in my opinion, the various baths that are advised, such as those of Nauheim are more suitable for functional than for valvular diseases. Indeed, they are of no use in stationary lesions, and are hazardous in the extreme where there is extensive dilatation. When venous engorgement is excessive, and there is manifest distress therefrom, much relief can be obtained through venesection. A concentrated solution of magnesium sulphate taken about an hour before breakfast is a valuable means of depletion through the bowels especially when there is much anasarca. Some of the disturbing symptoms of valvular disease are frequently best alleviated by small repeated doses of calomel and soda bicarbonate. After more than twenty-five years experience in the employment of digitalis in heart affections, my conviction is that properly used and in its purity it is one of the few drugs that are indispensable. It matters not what valve is affected, some preparation of digitalis, preferably the tincture or the infusion, is the remedy for ruptured compensation. Contrariwise, it can

only work mischief where there is a perfect adjustment between the means and the avenues of circulation.

In consultation with a practitioner, who was strongly prejudiced by his previous training against the use of digitalis in aortic lesions, he could not be persuaded to give it in a case of aortic and mitral insufficiency that was in the extremes of a destroyed compensation. The drug was prescribed, however, and in large doses with results that were efficacious. Digitalis, slows the heart and strengthens its contractions, and that meantime it allows somewhat fuller regurgitation, and also increases tension in the peripheral arteries, is no argument against its supreme usefulness. The proof of the value of the remedy rests upon the good results that have followed its employment, and not upon theorizing in regard to the imaginary consequences of prolonged diastole or of increase in arterial pressure. Manifestly there are conditions of the heart that are beyond the help even of digitalis. Sometimes, however, it fails to act, owing to a lack of purity, or to inadequate dosage, or to physical impediments. For instance, there was a young woman under my care with valvular disease that was so affected by the mechanical pressure of a consequent dropsy that medicine would not act upon the heart, kidneys, or even the bowels until her legs had been punctured and the general tension removed. A man came to me some years ago who was so dropsical that he was literally water-logged. He had been taking eight minims of the tincture of digitalis, four times a day, without the desired results. An increase of the dose to twenty minims was all that was needed to entirely remove the anasarca. Formerly a woman was put under my care in a similar condition, and she had to have the legs punctured, the chest aspirated, and repeated doses of a concentrated solution of magnesia sulphate, before she began to react to the digitalis. Now and then it is necessary, on account of a fault in the selection or the preparation of the crude drug, to seek a new source of supply if the digitalis is not working with satisfaction. The dose of the tincture of this drug varies from ten to twenty minims, and of the infusion from one to four drams, according to the urgency of the case, and to individual idiosyncrasies. It should not be repeated, for any length of time, more often than once in three or four hours, and when large doses are being taken the patient should maintain a recumbent position. The poisonous effects of digitalis are nausea and vomiting, decrease in the quantity of urine, fulness and slowness of the pulse followed by smallness and irregularity, with violent cardiac palpitation; its beneficial results are shown by relief of dyspnea, disappearance of dropsy, and cyanosis, and by increased strength, fulness, and steadiness of the pulse, together with an abundant renal secretion. As medical examiner for many years of a number of young physicians, quite above the average in attainments, competing for positions upon the house-staff of one of our large hospitals, my opinion is, if I may be pardoned for the digression, that, while remarkably well informed in most respects, a certain portion of them are lamentably deficient in a knowledge of the untoward and the toxic effects of the potent drugs they are expected to prescribe. It would seem wiser to burden their minds, in the teaching, with a smaller number of remedies, and to charge them with the vital importance of knowing all about the few that are essential, so that they may be able to readily distinguish between what is due to disease and what is sometimes the outcome of medication. The correct use of so powerful a remedy as digitalis predicates always the utmost watchfulness. Drugs at best are double-edged tools and require careful handling. Of all the substitutes for digitalis, the most valuable is strophanthus. It should be given in about five-minim doses once in four hours.

Strychnine is an excellent heart tonic but its use in large doses should not be continuously prolonged as it is liable to result in exhaustion. Nitroglycerin is available to relieve undue tension of the arteries, and it and digitalis are sometimes given with benefit in conjunction. Acetate of potash in sufficiently large amounts acts well when a diuretic is required. A free movement of the bowels with magnesia sulphate often will promote a desired action of the kidneys. In palpitation where there is excessive hypertrophy, the tincture of aconite in three minim doses every four hours is beneficial. Whenever valvular disease is complicated by anemia and malnutrition, which is not seldom, Fowler's solution of arsenic and the tincture of the chloride of iron are indicated in connection with nutritious food. Morphine and atropine combined, when simpler remedies fail, are helpful in palpitation, restlessness and sleeplessness. Small doses of these two drugs are often efficient in relieving cardiac pain and dyspnea. In full doses morphine is dangerous in pulmonary edema. The shortness of breath and distress caused by this condition must be treated by digitalis, by dry cupping, and by catharsis, and, when associated with cyanosis, venesection. Since this transudation of serum into the air cells is probably due in many instances, according to Welch, to an especial weakness of the left ventricle, digitalis is the chief reliance, but, when the entire lung has become edematous, the outlook despite every expedient is commonly hopeless. During my service last winter there was a patient, who, with a valvular disease, was suffering from a hitherto unaccountable orthopnea. It proved to be due to a large effusion in the right pleural cavity, and immediate relief was brought about by aspiration. Hydrothorax either bilateral or unilateral is a cause of difficult breathing that is now and then overlooked. Granting this to be the case, a withdrawal of the fluid is indicated, and should there be also a passive effusion in the pericardium the operation will facilitate its reabsorption. Puncturing the legs of a patient with extensive edema, under aseptic precautions, is a safe and most useful procedure.

When compensation has been reestablished, it

is well to begin with gentle massage, followed by resistance movements, and finally, where practicable, to enjoin pedestrianism. A daily walk in the fresh air out of doors, short in the beginning and cautiously increasing the distance, is nearly always salutary. Those who neglect this systematic exercise are apt to suffer in consequence. The pains and aches that often deter a person from making any exertion, and even the palpitation, frequently are overcome by persisting in that which originally caused the discomfort. With the circulation again in equilibrium digitalis may be entirely given up for the time being, or continued in small doses if it seems preferable indefinitely. Just how long a given case will survive the first serious break in the compensation under even the most intelligent direction is a difficult question to answer.

A great deal depends upon what is more or less beyond clinical observation. For example, the extent of histopathological disintegration in the heart itself. When the lesion is the result of an extinct endocarditis, instead of an ever advancing sclerosis, the integrity of the cardiac muscle is more apt to be preserved, and the outlook correspondingly encouraging. A patient suffering from a valvular disease was brought into my ward upon a stretcher, in an absolutely helpless condition, with general edema including hydrothorax and hydropericardium. In a few weeks compensation was restored by appropriate treatment, and she walked out of the hospital and disappeared. About a year afterward, having in the meantime been entirely without medical care, she came to light in the same distressing predicament, with extensive edema of the lungs in addition, to which, in spite of renewed efforts in her behalf, she finally succumbed. There was a man in attendance at my clinic for eight years with a mitral stenosis, who had marked edema of the legs and thighs, and cyanosis of the lips and extremities when he first appeared. During this period, after the break in the compensation was repaired, he was able to do light work much of the time, though he was kept under regular medical inspection. A patient, aged fifty-six years, suffering from an excess of dilatation of the heart over hypertrophy entered my dispensary in March, 1900, with a large sacculated aneurism of the ascending aorta, and with aortic insufficiency and obstruction, and mitral regurgitation. His heart gave dulness on percussion for two and a half inches, on a level with the sternal insertion of the fourth rib, to the right of the median line, and six inches to the left, and from that same level down the sternum to one and a half inches below the ensiform cartilage. The balance was renewed between hypertrophy and dilatation and he has continued in a fairly good condition for three years, despite this enormous cardiac enlargement; an increase in the size of the heart that must exceed even the wide limits of the superficial area marked out by percussion, and yet the man goes about with relatively little discomfort. There was a lawyer who toward the close of a very active career consulted me in his eightieth year for a first rupture in the compensation of an evidently long-standing double aortic lesion with mitral regurgitation. He recovered and lived, despite numerous temporary relapses, for seven years thereafter, but, he was constantly under treatment and general supervision. My experience leads me to the conviction that it would be a wise precaution for every patient with heart disease who has once begun the downward journey of a failing compensation, if not previously, to place himself under the direction of his physician even during the intervals of illness when there is seemingly no such necessity. An approaching disturbance can then be detected early enough to ensure, what otherwise is without certainty, the prospects of restoration.

In connection with the subject of this monograph, the following history is offered in exemplification:

Mitral obstruction and insufficiency, with consequent tricuspid regurgitation; pulsating liver with probably hypertrophic cirrhosis.—Case.—P. A., aged thirty-four years; occupation, masseur; born in Germany; married; nineteen years a resident of this country; was admitted to my department of the New York Post-Graduate Dispensary in 1899, and brought to my clinic for examination. Family history unimportant; personal history: Never had the diseases of childhood; was always healthy up to his twenty-second year, when he had gonorrhea. He has been an intemperate drinker of beer for at least twelve years. Admits having sometimes drunk as much as a hundred glasses in twenty-four hours. His sexual proclivities have been unrestrained. Shortness of breath while walking first appeared about five years before coming to the dispensary. Two and a half years ago his abdomen became swollen, and it was tapped and a small amount of fluid withdrawn. Present complaint: Exceeding shortness of breath, and pain in the left side, on exertion; swelling of the legs; enlarged abdomen; prostration. Physical examination: Edema of the lower extremities; cyanosis of the lips and tips of the fingers; marked pulsation of the deep and superficial veins of the neck, especially of the right side, with venous regurgitation; ascites; veins on the surface of the abdomen prominent; dilated hypertrophy of both sides of the heart with an excess of dilatation; weak mitral systolic, presystolic and tricuspid cystolic murmurs; pulmonary and aortic second sounds not accentuated; liver enlarged; extends from the fourth rib in the right nipple line down below the free border of the ribs to the level of the umbilicus; a heaving expansile pulsation of the liver not communicated directly from the heart or the aorta, but from a regurgitation of the blood down the inferior vena cava into the hepatic veins themselves. Lungs slightly edematous. Treatment: Paracentesis abdominis; concentrated solution of magnesia sulphate one hour before breakfast; tincture of digitalis minims 15 every four hours; strychnine sulphate gr.

1/60 three times a day; dry diet and rest in bed as far as practicable.

In the course of a few weeks, there was no more dropsy of the peritoneum; heart sounds and murmurs became more distinct; edema disappeared, and, practically, the cyanosis; pulsation of the veins of the neck and of the liver gradually diminished; finally the tricuspid bruit was no longer distinguishable. The mitral systolic and presystolic murmurs remained, but the latter became inconstant. The compensation was restored, the tricuspid murmur cured, and the patient thus far maintains the established equilibrium.

Recapitulation.—Judicious treatment of a patient with valvular disease of the heart presupposes a knowledge of the distinction, and an ability to discriminate clinically, between adequate and inadequate compensation; possibility is one thing, probability is another, and finality quite another in the prognosis of these affections; although not always feasible, it is nevertheless desirable frankly to explain the situation, where dilatation from valvular defects is balanced by hypertrophy, in order to forestall a fortuitous disturbance of equilibrium; ordinary occupations and recreations not too strenuous need not necessarily be abandoned; systematic outdoor exercise, preferably walking, is not only permissible, but, to maintain the integrity of the heart muscles, actually indispensable; violent exertion, exciting emotions, and excessive eating and drinking are positively injurious; temperateness in all things pertaining to daily existence should be the watchword; with failing compensation absolute rest is of paramount importance, and, not infrequently, all that is necessary for rehabilitation; digitalis in this condition irrespective of the valve affected when drugs are required is the sole remedy that cannot be dispensed with; large doses may be given for a short time and small doses for a long time or indefinitely; strophanthus is one of the most reliable substitutes for digitalis; nitroglycerin, calomel, aconite, iron, arsenic, magnesium sulphate, and strychnine are valuable adjuvants; maximum doses of strychnine should not be continued for extended periods without intermission; finally, ruptured compensation is the beginning of the end, however long deferred by intelligent management.

115 East Thirty-fourth Street.

Post-mortem Irritability in Nerves.—In comparing the differences in irritability between the nerves of animals which have been anesthetized for some hours before death, and those of animals which have not been so treated, W. D. Cutter and P. K. Gilman (Proc. Am. Physiol. Soc., Am. Jour. Physiol., Feb. 1, 1904) found that the nerve removed from the anesthetized and cooled animal survives for a longer time than that taken from the animal at the beginning of the period of anesthesia, the difference in time of survival being as much as four or five hours. A more marked difference, however, is that the anesthetized nerve exhibits throughout a much greater irritability.

THE CLINICAL SIGNIFICANCE OF PAIN IN THE EPIGASTRIUM.*

BY FRANK H. MURDOCH, M.D.,
OF PITTSBURG, PA.

Pain in the epigastrium may be due to hyperacidity, hypersecretion, hyperesthesia of the stomach, nervous gastralgia, biliary colic, certain affections of the spinal cord, cancer, gastric ulcer, pancreatitis, some forms of appendicitis, and Addison's disease.

The pain of hyperacidity comes on one or two hours after meals, and ceases at the end of the digestive period. It may be temporarily relieved by the ingestion of food or alkalies. There is sometimes general tenderness over the whole epigastric region; but pressure never causes actual pain.

The pain of periodic hypersecretion comes on suddenly in the midst of perfect health. Besides pain there is extreme thirst and vomiting of large quantities of hot sour fluid, which upon examination proves to be gastric juice. Even if no food or drink is taken, the stomach in a few hours fills up again, to be again emptied by vomiting. The patient becomes greatly exhausted, his pulse grows feeble and his extremities cold. These symptoms may continue for two or three days, then suddenly disappear; and the patient in an astonishingly short space of time be restored to health. The following is a typical case of periodic hypersecretion so far as symptomatology is concerned; but instead of the hypersecretion being due to a neurosis, it was the result of gastric ulcer:

Case I.—On October 21, 1899, J. R., hotelkeeper, thirty-three years of age, consulted me in regard to his stomach and gave the following history. During the latter part of 1897 he began to be troubled with distress after meals, and much bloating and belching. On Thanksgiving Day, 1898, he became suddenly ill, and was at once obliged to assume the recumbent position. During the first three days and nights of his illness he experienced, every two or three hours, severe pain in the gastric region, which was temporarily relieved by vomiting a large qauntity of hot sour fluid. He also suffered greatly from intense thirst, and became so exhausted that he was scarcely able to turn himself in bed. At the end of three days the pain and vomiting ceased, so that he was able to retain liquid food; after which time he began to improve rapidly. He was in bed altogether two weeks, and during that period lost fifty pounds in weight; but from the time he was able to leave his room, his recovery was as rapid as the onset of his illness had been sudden; for in a month his health was completely restored and he had fully regained the weight he had lost. He had a second attack in February, 1899, a third in September, 1899, a fourth in April, 1900, and a fifth in June, 1900. A specimen of the vomit sent to me during one of these attacks proved upon examination to be gastric juice, mixed with

* Read at a meeting of the Pittsburg Academy of Medicine.

food particles, Töpfer's test showing that free hydrochloric acid was present in more than normal amount. He had during the period before mentioned two hemorrhages from the stomach, one following and the other preceding an attack of hypersecretion.

The chronic form of hypersecretion, commonly called Reichmann's disease, is usually associated with hyperacidity. There are pains in the epigastrium which come on two or three hours after meals. Very soon vomiting appears as a new symptom. At first it occurs only occasionally but later on two or three times a day, sometimes it also occurs in the early morning (about two or three o'clock) and is then preceded by a long and severe attack of pain (Einhorn).

In patients suffering from chronic hypersecretion, the stomach always contains gastric juice in the fasting condition; and this is the most important point characteristic of the disease.

Case II.—On January 23, 1900, T. W., aged fifty-six years consulted me in regard to his stomach and gave the following history: Twenty years ago he had a hemorrhage from the stomach which greatly weakened him. After the hemorrhage he was in bed for a month, and lived during that time on liquid food. Ever since he has been troubled with constipation, and has had attacks of vomiting once or twice a year. In April, 1899, he had such an attack, and for a week blood appeared in his stools and also in the vomit. In the autumn of 1899 he spent a month in England, returning October 28. During this trip he felt perfectly well, his bowels moved naturally, and he did not vomit. Soon after reaching home, however, his bowels became constipated, and vomiting returned. Since November 28, 1899, till the present time, that is about two months, his bowels have never moved without an enema; and he has had attacks of severe pain associated with extreme thirst and vomiting. At first the vomiting occurred only at night, about one or two o'clock, the vomit being large in quantity and very acid. Lately he has been vomiting two or three times a day, usually from two to four hours after meals.

Physical Examination.—Chest intact, liver normal, stomach and descending colon full of gas. Knee-jerks present, pupils respond to light and accommodation. Examination of stomach contents after Ewald's test meal shows that free hydrochloric acid is present in excess, Töpfer's test giving an acidity of 44, total acidity 56. His urine was always alkaline after an attack of vomiting, but did not at any time contain sugar or albumin.

Jan. 24. Last evening, five and a half hours after supper, shooting pains began in his epigastrium, and extended through to the subscapular region. In seven and a half hours after supper he induced vomiting, which did not relieve the pain, and he did not sleep until five o'clock in the morning. The vomited matter presented a clear appearance and contained no food particles. Free hydrochloric acid was present, Töpfer's test giving an acidity of 28, total acidity 56. Erythrodextrin was present, but there was no trace of sugar.

Jan. 25. He ate for dinner last evening roast beef and toast and experienced no pain or vomiting during the night and slept well.

Jan. 26. Last evening he again ate roast beef and toast for supper. Two hours after this meal he had severe pain and vomited several times. Urine this morning alkaline.

Jan. 29. He ate for supper last night roast beef, dry toast and boiled rice. He had no pain or vomiting during the night. This morning, before he had eaten anything, I obtained by expression two ounces of liquid mixed with mucus; but the expressed fluid did not contain any food particles. I then washed his stomach, and found no rice grains in the wash water. Examination of the expressed fluid showed that free hydrochloric acid was present, Töpfer's test giving an acidity of 20, total acidity 32. No trace of sugar was found. The only point which throws any doubt upon the genuineness of this case is the history of the previous hemorrhage from the stomach. This patient left for home on February 6, that is, fourteen days after I first saw him; and since that time I have no written history of his case.

In hyperesthesia of the stomach, the pain does not appear ten or twenty minutes after taking food, as in ulcer, but immediately after eating; it follows the ingestion of liquids as well as solids, and is only partially relieved by vomiting. There is no circumscribed spot of tenderness; but the whole epigastrium is sensitive to pressure (Fenwick).

In nervous gastralgia the pain is intense; either sharply localized or diffuse. Patients double themselves up to relax the abdominal muscles; and avoid deep breathing, coughing or speaking aloud. The face is pale, distorted with pain and covered with cold sweat; and there may be a condition of collapse, with a sensation of impending death, and attacks of unconsciousness. Sometimes the attack ends suddenly with vomiting; at other times the normal condition is restored gradually (Ewald).

In biliary colic the attacks of pain appear only at intervals, and have no relation to the taking of food. The pain comes on abruptly, and is chiefly referred to the right hypochondrium and umbilical region. There is usually tenderness over the situation of the gall-bladder; but pressure upon other parts of the abdomen often affords some relief. Chills and fever are common symptoms. Severe vomiting frequently occurs during a paroxysm; but emptying the stomach does not relieve the pain. Jaundice is apt to follow an attack (Fenwick).

The gastric crisis of tabes is thus described by Charcot: "Suddenly, and frequently with an attack of fulminating pains, the patient complains of pains which begin in the groins, ascend along

both sides of the abdomen to the epigastrium where they become fixed. At the same time there is almost uninterrupted and exceeding painful vomiting, the vomit consists at first of food, later of a mucous fluid which is sometimes mixed with bile or tinged with blood. This is accompanied by marked nausea and vertigo as well as by cardialgic pains which at times reach a terrible degree of intensity. These gastric pains may appear at the very beginning of the disease and then belong to the so-called pre-ataxic symptoms, but they may not disappear even when the disease has reached its full development with complete ataxia."

In cancer of the stomach pain is the most constant of all the symptoms, occurring, according to Brinton, in 92 per cent. of all cases. The pain begins at a comparatively early date and never entirely disappears, though there may be remissions and exacerbations. It is not localized to one spot, does not depend on the taking of food, has not the severe gastralgic paroxysms of ulcer and is not relieved by vomiting or by the completion of digestion.

The pain of gastric ulcer usually comes on from ten to twenty minutes after the ingestion of food, reaches its maximum at the end of two hours and disappears at the completion of gastric digestion. Frequently, however, vomiting occurs soon after meals, and this generally affords relief. In rare cases, the pain becomes continuous and, according to Fenwick, if the ulcer is situated near the pyloris, and is adherent to the pancreas, the distress is chiefly experienced in the intervals of digestion; and is temporarily relieved by food and draughts of water. I believe, however, that pain may be caused, two or three hours after meals, by a hyperacid juice coming in contact with the ulcer, and this condition is also temporarily relieved by food or alkalies.

In suppurative or perforating appendicitis the patient is seized with violent pains in the abdomen which at first may be felt either over the entire abdomen, on the left side of the abdomen, or in the epigastric region, but very soon they settle in the right iliac region (Einhorn).

In regard to pain in the epigastrium, resulting from disease of the pancreas, I will simply quote from Robson and Moynihan on Diseases of the Pancreas, a work published in October, 1902: "Pancreatitis may be acute, subacute or chronic." Fitz says, "Acute pancreatitis is to be suspected when a previously healthy person or sufferer from occasional attacks of indigestion is suddenly seized with violent pain in the epigastrium followed by vomiting and collapse, and in the course of twenty-four hours by a circumscribed swelling, tympanitic or resistant, with slight rise of temperature."

"Between subacute pancreatitis and acute pancreatitis no hard and fast line can be drawn. The former has usually a sudden onset with acute pain and vomiting associated with constipation; but the collapse is not so marked as in the acute form, and may even be absent. The upper abdominal region does not become so rapidly swollen, and vomiting is less severe, and less prolonged. At other times the onset may be more gradual, although the symptoms may be similar. Tenderness over the pancreas is well marked, and, on account of the tympanites being less than in the acute form, it may be possible to feel the swollen gland, especially under an anesthetic. Constipation gives place to diarrhea, and pus or blood may be noticed in the stools which have a very fetid odor. The pulse is less rapid and less thready than in the acute form, and the temperature is more regular. We have seen the temperature reaching 104 and 105° F. and yet the pulse to vary between 90 and 100. The morning temperature may be normal and the evening temperature high for several days or even weeks. The pain occurs in paroxysms, but there is also a constant dull pain at the epigastrium. The patient may lose the more urgent symptoms and appear to be really improving; but the loss of flesh and feebleness continue and relapses usually occur, leaving the patient more and more feeble until death supervenes from asthenia. Albuminuria is pretty constant, but glycosuria is rarely present, and lipuria is an unusual symptom. Chronic pancreatitis is quite distinct from the acute or subacute form, although it is possible that some of the latter cases end in chronic interstitial pancreatitis. As clinically seen, it usually arises by extension of the inflammation from a chronic catarrh of the pancreatic duct extending from a gastro-duodenal catarrh, though it is frequently associated with biliary or pancreatic lithiasis or with gastric, pyloric or duodenal ulcer. Its course varies. The onset may be quite gradual and painless, or it may be ushered in by a severe pain at the epigastrium, followed by jaundice resembling a gall-stone attack, and associated with nausea and vomiting, and perhaps followed by a feeling of chilliness or even a rigor. The pain, however, is not over the gall-bladder, and does not pass around the right side to the subscapular region, but is central, and passes backward to the mid-scapular region or around to the left side; thus resembling stomach rather than gall-bladder pain. Tender spot is usually above the umbilicus in the middle line, and not over the gall-bladder, as in cholelithiasis. When once jaundice has come on it tends to deepen with each attack, until it becomes continuous and chronic. The paroxysms of pain may be repeated more or less frequently, or there may be no paroxysmal pain, merely a dull ache deeply seated, burning and boring in character. A swelling of the pancreas may sometimes be made out, but as the recti are rigid because of pain and tenderness in the epigastrium, it can usually only be discovered under anesthesia. Loss of flesh and strength are well-marked symptoms in all cases. Vomiting in some cases may be absent, but there are usually a want of appetite and flatulent dyspepsia, and always a sense of fulness and weight at the epigastrium

for some time after food. Jaundice is not necessarily present at first, though it is usually present at some stage of the disease and is often well marked; but, as was pointed out some years ago by Claude Bernard and by Dr. Walker, of Peterboro, the stools are white, even when the pancreatic fluid alone is absent from the intestine. Diarrhea is often present and the stools are offensive and may be fatty. Albuminuria is common, and glycosuria may occur, but the latter is probably only present in cases where the whole gland is affected or where the islands of Langerhans are involved. Fever may be absent, but in some cases the temperature runs a hectic course, always rising in the evening and falling in the morning. This is especially the case where ague-like paroxysms occur.

In Addison's disease there is often intense pain in the epigastrium, radiating to the hypochondriac regions and sometimes by reason of its intensity dominating all other symptoms of the disease. Previous to the appearance of the digestive disturbances and epigastric pain there is, however, a permanent sense of weakness and exhaustion, the lack of power and debility frequently presenting a striking contrast to the relatively good general appearance of the patient and the abundance of abdominal fat (Neusser).

THE SIGNIFICANCE OF PUS AND BLOOD IN THE URINE.*

BY RICHARD DOUGLAS, M.D.,
OF NASHVILLE, TENN.

There is nothing unique, sensational or pretentious in this subject. The clinical significance of pus and blood in the urine may interest only a few, yet, if I have observed correctly, these physical phenomena receive but scant consideration. Special workers in genito-urinary surgery have for the last fifteen years written eloquently of, and demonstrated skilfully, the improvements in diagnosis in this line, and yet many do not realize that in diseases of the urinary organs, more perhaps, than in any other system in the body, success depends upon an early and accurate diagnosis and prompt interference. In the entire category of diseases of the urinary organs, pyuria and hematuria are more constantly present and more diagnostically significant than any other symptoms. This affords sufficient reason for a close analytical study of these symptoms.

Pyuria.—Given a specimen of urine containing pus, the clinician's duty is to determine the source of this abnormal constituent and there, possibly, to discover its cause and direct the treatment. That the finding of the court of inquiry may be errorless, all evidence, direct and circumstantial, must be taken.

Family history has its bearing, an hereditary predisposition to tuberculosis, rheumatism or cancer should be considered. More especially should we ascertain the personal history of the patient. This, of course, is significant when it reveals diseases of the urinary organs; yet it is none the less important to take note of certain constitutional ailments in the course of which complications involving the kidneys occur.

If we will proceed in this systematic manner, we are directed in our search to the seat of trouble and greatly aided in determining the etiological pathology. When possessed of all collateral information obtainable, we should in every case of pus in the urine conduct our examination from the meatus urinarius inward along the urinary tract until the seat of disease is discovered.

Urethra.—In both male and female, pus from urethral disease ordinarily flows spontaneously from the meatus, or may be squeezed or expressed therefrom. In the male, in deep-seated urethral inflammation, the pus may not be in sufficient quantity to be so detected. You may then employ the "two-glass" test, *i.e.*, have the patient to void urine first into one glass, then after an ounce, say, is passed, catch the remainder of the urine in a second glass. If the pus is from the urethra, the urine in the first glass contains pus and shreds, while that in the other is clear. If both specimens are cloudy, it shows that there is some involvement internal to the vesical sphincter. In women, especially those infected with gonorrhea, pus may be squeezed from the open mouths of Skene's ducts alongside the *meatus urinarius* or a peri-urethral abscess may discharge through the meatus.

Pus of urethral origin is thus easily recognized. Coupled with the history and associate symptoms, the diagnosis is readily made. Should, however, our investigation eliminate all pus producing diseases of the anterior urinary tract and the catheter specimen of vesical urine contain pus, we must now enter upon a most careful analytical search to determine its source. Is the pus from the bladder? Is it from the ureters or kidneys, or, perchance, may it come from some extravesical but communicating suppurating focus?

The chemical analysis of the urine gives us our first clue. If the urine be alkaline, the pus is probably of bladder origin. Rosenfeld* claims that "the greatest differential point is the quantity of albumin in the urine. If the pus proceed from the bladder, the albumin is low; about 1.5 per cent. or less. If from the kidney, 3 per cent. or more." His explanation is that the kidney, which is the seat of purulent infection, is almost certain to secrete albuminous urine.

A microscopical examination of the centrifugalized urine containing pus will also show an abundance of epithelia. Many expert urologists attach the greatest consequence to the character of epithelium in localizing the seat of inflammation. Guiteras† holds that the kind of epithelium points quite clearly to the seat of inflammation; and Manley contends that upon it alone we may elucidate the diagnosis, while Osler, Musser and

* Read before the Middle Tennessee Medical Association, November 19, 1903.

* La Sem. Med., Mar. 26, 1902.
† Medical Record, Nov. 8, 1902.

Tyson all practically disregard it as determining the source of pyuria. We should be inclined to hold that an abundance of vesical pavement epithelium would indicate cystitis. We cannot, and should not rely upon the chemical and microscopical test. They are merely aids to a diagnosis. There are several intravesical diseases supplying pus to contaminate the urine in the bladder.

Prostatic enlargement in old men with residual urine invites infection by catheterization or otherwise. The pus from prostatic abscess and suppurating seminal vesicles in young men may overflow the sphincter and contaminate bladder urine. Careful rectal and bimanual examination should discover these conditions.

Inflammation of the bladder characterized by frequent and painful micturition, pyuria, hematuria, etc., is almost universally held to be a very common affection.

The revelations of the cystoscope have convinced many of us that the teaching of Kelly is correct, that "universal cystitis is a very rare affection, especially in women." It is quite a common picture to find the trigonum inflamed; but rarely the entire bladder; and that condition so frequently designated as cystitis, is due to some definite intravesical disease other than mere infection, or else a localized inflammation. But more frequently it is irritability of the bladder, symptomatic of disease elsewhere. Yet inflammation of the bladder is one of the most common sources of pyuria, recognized by its classical symptoms, presumably, and definitely determined only by cystoscopic examination.

After infection, the most common cause of vesical pyuria, is a foreign body in the bladder, usually a calculus. Its presence is readily recognized by the sound, bimanual examination and cystoscopy. In cases of enlarged prostate and pouching of the bladder, a stone may escape ready detection and in these subjects, cystoscopy is often very difficult and unsatisfactory on account of the hemorrhage. In these cases where the symptoms point very directly to vesical trouble, and in which the diagnosis is not determined by the ordinary means, Fenwick advocates, and has employed for ten years, supravesical cystoscopy—a method of examination not likely to become popular.

Ulceration of the bladder is rarely a primary disease, but its symptom—pyuria—may be one of its first clinical manifestations. It is usually of tuberculous nature, secondary to tuberculous infection of the genitals or kidney. Yet, we may find, as both Casper and Newman have taught, a single, simple ulcer of the bladder. Tumors of the bladder seldom cause pyuria in their early stage, unless they obstruct the urethral opening and give rise to urinary retention. Hemorrhage more frequently proclaims their presence.

Pyuria is the outcome of infection, introduced from without or occurring from the bowel under inviting conditions, and is a late symptom of vesical tumor. The presence of vesical neoplasms is made known by the symptoms, hematuria, vesical pain and tenesmus, reflex renal pain and the detection of the tumor by bimanual and cystoscopic examination. If, in our examination, we have eliminated all vesical sources of pyuria, we must bear in mind that pus of extravesical origin often contaminates the urine. Suppurating foci in the pelvis pyosalpinx, dermoid cysts (Kelly), appendicitis (Keene), etc., may discharge purulent matter into the bladder. We command through the cystoscope such a thorough view of the entire inner surface of the bladder when that organ is inflated, that there should be no difficulty in discovering such an extravesical source of pyuria.

But to proceed along anatomical lines with our examination, there may be nothing in the bladder to account for the presence of pus. Where, then, should we look for the source of supply? The ureters are rarely the source of primary infection. They become involved by continuity with an ascending infection from the bladder, or descending infection from the kidney.

Renal suppuration inducing pyuria may be recognized in one of three ways: (1) By seeing the purulent flow from the ureteral orifice through the cystoscope; (2) by microscopic examination of the urine obtained from each kidney with the ureteral catheter or segregator. With bladder clean and properly inflated either with water or air, preferably the latter, the vesical orifice of the ureter is brought into view. The appearance of the mucous membrane about the orifice often tells the tale. If a ureter is in the habit of discharging purulent urine intermittently or continuously, its lips and surrounding mucous membrane are eroded, mammillated and congested. This is quite suggestive of an irritating discharge. In comparison with the healthy side, it may be conspicuously different. More conclusive, however, is it to see the purulent urine flowing from the orifice, while the opposite side puts forth intermittent jets of clear urine. It is equally important to find, upon different examinations, that sometimes there is no urine from one orifice, while the other discharges physiologically. This intermittent arrest of the ureteral discharge of purulent urine is quite diagnostic of pyonephrosis.

In order that we may observe pus or cloudy urine from the ureteral orifice, there must be quite a liberal admixture of pus. Microscopical quantities of pus may indicate just as serious a lesion as a copious discharge, and, therefore, we cannot always rely upon the cystoscopic view. If, then, we are still undecided as to the source of the microscopical quantities of pus, having eliminated all question of its vesical origin, what means have we of determining its renal source? The Harris segregator is an uncertain instrument. I have repeatedly tried it and regard it dangerously misleading. The only positive way of determining the renal origin of pyuria is, as before stated, in seeing the puriform fluid flow from the vesical orifice of the ureter, or else

microscopically examining the urine obtained through the ureteral catheter.

This leads us to the consideration of the last part of our subject: What renal conditions may give rise to pyuria? The common suppurative diseases of the kidney, viz., pyelitis, pyonephrosis, pyelonephritis and renal abscess may all intermittently or continuously mingle their pus with the urine. It is not the purpose of this paper to enter into the causes and symptoms of these conditions in detail, but let it suffice for the present, to say that pyelitis is frequently a secondary infection, ascending in character, consequent upon some obstruction and infection of the lower urinary tract. And so with pyelonephritis, while pyonephrosis is more frequently due to calculus, and renal abscess to the localization and pathological action of the *Bacillus tuberculosis* or some of the common pyogenic organisms. The microscopical examination of the purulent urine withdrawn through the ureteral catheter, will in a great measure differentiate these several conditions by showing the character of the epithelium, the character and quantity of cylinders and furthermore, the presence of the specific microorganism.

In pyelitis, the pyuria is constant; yet, when the ureteral catheter is introduced, the first urine collected will show the greater abundance of pus. If this urine is microscopically examined, epithelium from the pelvis of the kidney only may be found. But it is not by the ureteral catheter alone that we make the diagnosis of pyelitis. The history of the patient is valuable. We know that pyelitis is generally secondary to infection in the lower urinary tract, consequent upon obstruction. Hence it is quite common in those exhibiting urethral stricture, prostatic enlargement, vesical tumors and cystitis. Nor must we lose sight of the fact that it occurs as an infrequent sequela of certain exanthemata. It is usually an infection due to the *Bacillus coli communis.*

A form of pyelitis—and subsequently pyelonephritis—is occasionally met with in pregnancy. I have seen several such cases; one with Dr. Frank Glenn, of Nashville, another diagnosed, but not proven, with Dr. Witt, and a third case, recently, with Dr. McCampbell, of Nashville. It is a complication seldom observed until the latter months of pregnancy, attributable to compression of the ureter by the gravid uterus, and to infection with the colon bacillus. When a pregnant woman develops lumbar pain of sudden onset, usually with severe symptoms, viz., local tenderness, chill and pyrexia, with acid pyuria, we should think of this complication. It rarely requires surgical intervention, but *may* do so.

Pyelitis in children is of sufficient importance to deserve mention. It is especially common in infant girls. It is a colon bacillus infection and is quite frequently noticed as occurring after some inflammation about the anus or genitals. The points that guide us to its diagnosis are: Pus and mucus in the urine, the acid character of the urine, great variation in the temperature, pain on being moved, rigid lumbar muscles, and what is more to the point, says Thompson, "Unlike any other disease, except malaria in infancy, it causes rigors." As a complication of typhoid fever, pyelitis may occur. Garnier and Lardennois* formulate the following conclusions: "That typhoid fever can give rise to renal suppuration, pyelitis or pyonephrosis; that the signs often appear in the course of the fever, but it is usually not until after the convalescence that the diagnosis of renal involvement is made."

Pyelonephritis.—A suppurating kidney usually succeeds upon a pyelitis, but here the secretive structure of the kidney is involved and the urine contains, in addition to pus, epithelia from the tubules, tube casts and fragmented blood corpuscles. The serious constitutional involvement, the fluctuating temperature, the succession of chills, vomiting, general lethargy, a tendency to somnolence, marked decrease in the amount of urine, even to anuria, proclaim the character of this grave form of renal suppuration.

Pyonephrosis.—A retention of pus in the pelvis of the kidney may be suspected when the urine voided shows the presence of pus intermittently. The diagnosis of this condition becomes beautifully accurate, sometimes upon simple cystoscopic examination. A patient recently entrusted to my care by Dr. Thompson Anderson, of Nashville, was subjected to several cystoscopic examinations. Upon some occasions pure pus was seen to flow from the vesical orifice of the ureter. At other times nothing would pass, although the ureteral orifice would be kept in the field of vision for several minutes.

If the obstruction causing the pyonephrosis will permit the passage of a ureteral catheter, pus and blood in drops, drams or ounces may be withdrawn. If to this examination we link the symptoms of those conditions causing ureteral obstruction, such as calculus, movable kidney or ureteral compression, we should have no difficulty in arriving at a diagnosis.

Tuberculosis of the kidney involving its cortical structure, may not give rise to pyuria, but when the abscess opens into the pelvis of the kidney, the urine is contaminated. This urine is infectious.

Not infrequently we find the tuberculous ulcers in the bladder and ureters. A presumptive diagnosis of this variety of renal tuberculosis may be made without a detectable number of bacilli in the urine, but the only conclusive evidence of renal tuberculosis is in finding Koch bacilli in the renal urine. Renal urine may become contaminated with pus from renal tumors, cystic and solid, echinococcal growths or from extrarenal sources, as in communication with appendiceal, perirenal, gall-bladder and other suppurating foci.

In conclusion, we must regard pyuria only as a symptom of many pathological conditions, involving any of the several parts of the urinary tract. It is only of diagnostic value when we

* La Presse Médicale, April 13, 1901.

ascertain its source; and he will be the most successful in his treatment who is most searching in his investigations.

Hematuria.—The appearance of blood in the urine is alarming to the patient and he insistently demands of the attending physician that he offer an explanation of its cause, and afford means of relief. The careful and conscientious attendant realizes that it is only a symptom of a pathological process somewhere in the urinary tract, and should proceed to ascertain the seat of lesion by exclusion. There are certain facts possessing general diagnostic value in hematuria, and to these we should give consideration. The family history, as we shall show later on, has its bearing. Indeed, there is a form of hematuria known as congenital of familial. Other individuals have, by inheritance, tuberculous, gouty or rheumatic tendencies. Constitutional conditions not infrequently are the cause of hematuria. Place of residence is of importance; in tropical countries, parasitic hematuria is not infrequent. Previous illnesses and conditions may direct us in the right lines of inquiry. It is quite important that we take cognizance of the age of the patient. It is further important that we ascertain under what conditions the blood is observed in the urine. Does it flow spontaneously from the penis as in urethral inflammation? Is it expressed by a contraction of the bladder at the close of micturition as in prostatic and vesical troubles? Does it occur symptomlessly, or is its flow preceded or attended by pain pointing in the one case to tumor, in the other to calculus? Is it augmented by exercise, and allayed by rest, as in renal calculus? Is it associated with active disease phenomena in other organs, as we find tuberculosis of the kidney often complicated with similar deposits in the lungs and pleuræ? So do we find nephritis with hemorrhage, complicated with cardiac changes, and an enlarged spleen may explain the hemoglobinuria of malaria. All facts bearing upon the general and local conditions of the patient must pass under our review, for be we ever so skilful in our investigations, there will remain a few cases in which the pathogenesis is obscure.

While I attach the greatest value to the cystoscope and ureteral catheterization in determining the source of hematuria, I am not one who is prone to hastily attach my faith to new things, to the utter disregard of old and tried methods. "The friends thou hast and their adoption tried, grapple them to thy soul with hooks of steel." Furthermore, the cystoscope is not in the hands of every practitioner; there are conditions which preclude its use, and who among us will dare assert that ureteral catheterization is an easy performance? Therefore, let us be "old fogy" enough to consider for a few moments, the simpler methods of determining the source of blood in the urine; proving our conclusions, when necessary and feasible, by cystoscopy and ureteral catheterization. To avoid repetition, we will take up these questions separately in considering hemorrhage of the several parts of the urinary tract from without inward.

The detection of blood in the urine is usually simple enough by ocular examination of the specimen. The color of the urine mixed with blood varies from a rosy tint to scarlet red, dark brown or black according to the quantity of blood and the length of time it is retained after its escape from the vessels. The chemical tests, while accurate enough, are more troublesome than the microscopical test, therefore the microscope is preferred for the detection of minute quantities of blood, insufficient to colorize the urine. The presence of blood having been determined it is now our duty to ascertain its source.

When blood occurs from the urinary tract anterior to the urethral muscle, the blood, if in sufficient quantity, will spontaneously escape from the meatus or the "two-glass" test may be tried. If the hemorrhage is from the prostatic portion of the urethra, the blood is passed with the first portion of the urine only; if the bleeding is of small quantity. If the bleeding is more copious, the pressure of the blood overcomes the resistance of the internal sphincter, and the bladder urine is admixed with blood. In general we may say that urethral hemorrhage occurs independently of micturition, or with the first portion of the stream, and, if profuse, is passed in long thick clots. In prostatic hemorrhage of moderate amount, there is blood both at beginning and close of urination. If profuse hemorrhage, it mixes with the bladder urine.

I shall not enter into detail upon the causes of urethral and prostatic hemorrhage—they are known to us all—but proceed at once to the consideration of hemorrhage from the bladder. The common causes of hemorrhage from the bladder are: Cystitis, stone, neoplasm and tuberculous ulceration. Cystitis, as we have elswhere remarked, rarely develops except as a complication of other conditions. The history of the patient, the opportunity for instrumental infection, followed by the distressingly acute symptoms—polyuria, dysuria, pyuria, hematuria and the constitutional impression—as denoted by general discomfort, chill and fever, are usually sufficient to declare a diagnosis in the acute stage. In the chronic condition, cystoscopy is necessary to eliminate simulating conditions.

A stone in the urinary bladder rarely causes profuse bleeding; the blood is intimately mixed with the urine which also contains mucus, pus and crystals. The hemorrhage is induced by exercise and is allayed by rest, and oftentimes the bleeding is most profuse at the close of micturition. These facts, accompanied by the other classical symptoms, point very clearly to vesical calculus. The positive diagnosis of its presence is made by bimanual examination, sounding and cystoscopy.

Tumors of the bladder in a large percentage of cases,—84 per cent. says Fenwick—make known their presence by the occurrence of hemorrhage. The bleeding occurs at the end of urination. It is spontaneous and unaccompanied by other

symptoms. It may be insignificant in quantity, rarely profuse at the outset. This symptomless hemorrhage is characteristic of vesical tumors. It may continue for a few days and then cease. Its recurrence may be postponed for weeks, months or years. It is in some measure controlled by rest. The feature to be noted in connection with it is, that at first hematuria from bladder tumors is unaccompanied by other symptoms. In advanced cases we have engrafted the symptoms of infection upon obstruction to the outflow of urine and also of ureteral obstruction as signalized by the renal ache. We should try and make our diagnosis by bimanual examination. The great danger to be feared in tumors of the bladder, is infection. Therefore, cystoscopy must be most aseptically conducted. The hindrances to this method of examination are sometimes insurmountable; we may find it difficult to get the bladder sufficiently clear of blood; the beak of the cystoscope, though judiciously handled, excites additional hemorrhage, and when the growth is large, we may be unable to pass the cystoscope or succeed in inflating the bladder. It is, however, by the aid of this instrument that we gain the most accurate idea of the character, location and seat of these growths.

Tuberculous Cystitis.—When cystitis develops without some apparent cause and persists in spite of treatment, we should think of the possibility of it being tuberculous. In such cases, frequent urination and hematuria, moderate in amount, are the leading symptoms. Our diagnosis rests upon the discovery of tuberculous lesion in the epididymis, prostate, or seminal vesicles, or, as I believe, more frequently in the kidney. The cystoscope shows tubercles, disseminated or grouped over the mucous surface of the bladder, or else ragged, irregular necrotic ulcers, and the final and conclusive test is finding tuberculous bacilli in the urine. In pregnancy, the pressure is sometimes so great that the vesical veins become varicose and rupture. This is one of the exceptional causes of hematuria during pregnancy. Similar conditions have been recognized in fibroid and other abdominal tumors.

Renal Hemorrhage.—The diagnosis of hematuria of renal origin is based upon the following points: (1) If the blood is thoroughly mixed with the urine, appearing with the first and terminal flow, it is presumptive, though not conclusive of renal hemorrhage. (2) When the bleeding is profuse from the kidney, long worm-like decolorized blood clots are passed. They are much thicker, lighter in color, than the clots passed from ureteral or bladder hemorrhage. In one instance in my own experience, the clots, some three inches long, were mistaken for a lumbricoid. Mr. Morris records an instance where he opened a bladder suprapubically and removed a mass consisting of a cord the diameter of a pen holder, 6½ inches in length, of unbroken blood clot. The source of microscopical quantities of blood is not so easily located. If the blood cells are found crenated and fragmented, it rather indicates their renal origin. A great proportion of albumin would further suggest the kidney as the seat of trouble, but the only conclusive test of renal hemorrhage is the view obtained through the cystoscope or the examination of a specimen of urine from the ureteral catheter. It must not be inferred from this statement, that it is necessary at all times to subject a patient to intravesical examination to satisfy ourselves clinically, of the renal source of hematuria. There are many symptoms and physical signs occurring in the course of renal pathology, upon which we may make a working diagnosis without resorting to these modern and refined methods. Furthermore, the amount of hemorrhage may preclude the intravesical examination.

There are many causes for renal hemorrhage: Calculus, traumatism, tumors, tuberculosis, nephritis and movable kidney are the most common; hematuria is also met with as the result of the mechanical irritating effect of uric acid as a complication of various constitutional disease, especially the exanthemata and malaria. Exceptionally it occurs during pregnancy or following the administration of certain drugs; and in tropical countries, from parasites. There is a class of hematurics in which we are unable to ascertain the cause described by Klemperer as "essential" or "angioneurotic." In this class may be included cases of neuralgic hematuria and hemophiliacs. We do not presume in every case to be able to assign the cause for the hematuria, but the quantity, the character of bleeding, the time of its occurrence, conditions exciting it, other urinary phenomena and the general symptoms attending it, will in many instances enable us to very definitely declare a pathological diagnosis.

Denaclara* says, "In tumors of the kidney, hematuria occurs as a symptom in from 40 to 68.88 per cent." It has the following characteristics, according to Guilet: (1) it is often spontaneous; (2) it is not influenced by repose or exertion; (3) it occurs at any period of the disease; (4) it is repeated at variable intervals; (5) it is usually profuse; (6) lasts from one to six days; (7) it is often preceded by pain. As further aids to the diagnosis of renal tumor, we find the presence of tumor, the age of the patient, perhaps glandular involvement, in many cases varicocele, and often a very serious grade of constitutional cachexia.

Renal Calculus.—Hematuria due to a stone in the kidney is traumatic in nature. The hemorrhage proceeds from the pelvis of the kidney usually. The urine, therefore, does not contain blood casts. Of course, exceptionally the calculus may be imbedded in any portion of the cortical substance of the kidney, exciting a nephritis, the urine showing casts and albumin. Other symptoms precede the occurrence of hemorrhage as a rule. The amount of blood is usually very slight, generally microscopic in quantity, though it may be copious. The blood appears after exercise and disappears on rest; is quite noticeable

* Thèse de Lyon, 1899.

after an attack of renal colic. A small, rough stone may excite profuse bleeding.

Renal Tuberculosis.—Pousson believed that tuberculosis of the kidney, like pulmonary phthisis, passes through a stage of congestion before it reaches suppuration. Newman records cases of hematuria of four years, and one of thirteen years before evidence of renal tuberculosis became decisive, and I have seen one case—patient of Dr. Harrison, of Columbia—in which hemorrhage antedated by six years all other symptoms. In support of this idea, of congestion, hematuria is often the earliest symptom of renal tuberculosis. Therefore, a spontaneous appearance of blood in the urine, unaccompanied by other symptoms, should suggest renal tuberculosis; but usually these first hemorrhages are microscopical in quantity, and we are led to their detection only when there is frequent urination, especially at night, which is a strong suggestive symptom of renal tuberculosis. In the more advanced stages, when there is breaking down of the tuberculous abscess, hematuria is more constant and may be copious. It is mingled with pus and débris. As a rule, the hematuria from tuberculosis is scant in quantity, intermittent in its appearance and is not excited by exercise. In two instances I have observed alarming hemorrhage from tuberculous kidneys. We may infer the nature of the exciting cause, if the individual is a female somewhat under middle age; if she has complained of polyuria; has hectic phenomena and digestive disturbances. Further suspicious evidence would be the detection of healed or active tuberculosis in other organs. A tuberculous kidney is not necessarily an enlarged kidney, and it may be quite movable. Microscopically, the urine shows leucocytes, fat globules, pus, red corpuscles and shrunken epithelium. If the bacilli of Koch are found, it is conclusive evidence of the tuberculous process. Yet, thus far, we have not determined conclusively that the seat of trouble is in the kidney. The findings in the bladder urine may be sometimes misleading. We can definitely locate the source of the hemorrhage only by cystoscopy and perhaps it may be necessary to use the ureteral catheter. These methods will definitely incriminate the guilty organ, and, what is of equal importance, show the condition and efficiency of the other kidney.

Nephritis.—Abundant unilateral renal hematuria may occur in subacute and chronic nephritis. Senator does not believe in unilateral Bright's disease. Belfield has collected 55 cases of chronic renal hemorrhage proven by one of the sure ways of diagnosis; 18 of these showed chronic nephritis. This, then, is one of the common causes of hematuria. These cases are especially suitable for the Edebohls' operation.

Movable Kidney.—It is no unusual thing to meet with hematuria in movable kidney. It is a passive hemorrhage, generally, attributed to torsion of the renal vessels. Movable kidneys do not twist their pedicles; they simply glide downward, and the explanation of the passive congestion is probably traction on the renal veins, inducing a passive hyperemia. This at first, as Newman explains, leads only to albuminous urine. Under increased hyperemia, blood appears. Cabot* records a case in which the blood lost reached such proportions as to induce serious anemia. It was controlled by placing the patient in Trendelenburg posture, and recurred when she assumed a standing position. This was a unique case, for, as a rule, the hemorrhage in a movable kidney, is only microscopical in quantity and not an essential feature in the diagnosis of this abnormality. Rovesing† reports a case of passive hematuria of the kidneys due to tight lacing.

Hematuria of Pregnancy.—In the Medical News, May 13, 1899, our President, Dr. Young, records an interesting case of hematuria of pregnancy. This phenomenon is very rare when due to the gravid state of the woman alone, excluding other specific causes. Bouman‡ has collected 17 cases. The pathogenesis may be ascribed to venustasis due to compression of the large abdominal vessels and of the ureter by the child's head in the pelvis. Chievetone regards it simply as a symptom of toxemia due to hepatorenal insufficiency. Of course these cases of hematuria during pregnancy become interesting only as a class when all recognizable causes are excluded. Ordinarily, constitutional treatment is sufficient. The hemorrhage ceases after delivery. Copious and uncontrollable hemorrhage may call for the interruption of gestation.

Gout and Rheumatism.—Hematuria may occur in rheumatism and gout. These cases are regarded by Musser as traumatic, analogous to calculus hematuria. An excess of salts mechanically irritates the kidney. The blood is microscopical in quantity, but none the less important.

Congenital, Hereditary or Family Hematuria.—In the *Lancet,* May 3, 1902, Guthrie reports that he has the knowledge of this form of hematuria in 12 persons, 8 of these were brothers and sisters or first cousins. Their mothers are two sisters who are themselves subject to this complaint. These two sisters had two brothers, both of whom were similarly affected. The author refers to Attlee's three cases of recurrent hematuria in one family. The characteristics of this form of hematuria are: (1) It is hereditary, familial and congenital. (2) It may be persistent for many years; it may be intermittent. (3) The paroxysms of hematuria are usually accompanied by pyrexia, headache, vomiting and lumbar pains. Duration of attacks usually several days. There may be months or years between attacks. (4) Not associated with ascites or the ordinary signs of nephritis. (5) It is not due to an excess of salts, nor is it attributable to any known eruptive disease.

We are all familiar with hematuria from certain drugs: Rhubarb, turpentine, etc., but I

* Boston Medical Journal, Feb. 27, 1902.
† British Medical Journal, Nov. 10, 1898.
‡ Monatsschrift f. Geb. u. Gyn., June, 1903.

deem it of some importance to call your attention to an observation of Langdon Brown* that it is now frequently suggested to administer urotropin throughout the course of enteric fever to prevent renal complications. He records two cases in which 10 grain doses of this drug, three times a day produced pronounced hematuria. Occasional cases of hematuria, due to Bilharzia hematobia are reported.

There yet remains a class of cases in which unilateral symptomless hematuria occurs. These cases are variously classified as (1) idiopathic, (2) essential, (3) angioneurotic or symptomless hematuria. The French Congress of Urology under the presidency of Guyon, discussed this form of hematuria, and were unanimously of the opinion that the terms were unnecessary and obstructive—mere confessions of ignorance. Klemperer is one of the few authorities who hold to the angioneurotic theory. Fortunately these cases are now, since the introduction of the cystoscope and ureteral catheterization, becoming very rare. Fenwick† has shown that in some of these cases at least, the bleeding emanates from the renal papillæ. It is fair to assume that many of them have a definite, though undiscovered, anatomical cause. But we are not yet prepared to say there is nothing in the angioneurotic theory. In this rather tedious review of an elementary subject, my sole purpose has been to impress upon my hearers, the urgent necessity of a painstaking analytical investigation of their cases showing pyuria and hematuria.

Upon one's ability to discover the source of these pathological constituents of urine, will corresponding success in treatment follow; or, as someone has said, "He who diagnoses well, treats well."

NEURASTHENIA.

BY HUBERT RICHARDSON, M.D.,
OF BALTIMORE, MD.;
LATE PATHOLOGIST TO MOUNT HOPE RETREAT; DEMONSTRATOR OF PHYSIOLOGICAL CHEMISTRY, UNIVERSITY OF MARYLAND.

Neurasthenia as a definite form of nervous disease was first described by Beard, of New York, in the *Boston Medical and Surgical Journal*, 1869, followed by a paper read before the New York Academy of Medicine in 1878; he further elaborated the subject in a work entitled "Nervous Exhaustion," which reached a second edition in 1890; later he published "Sexual Neurasthenia," where he attempts to place a number of different nervous troubles under the same heading, including hypochondria, hysteria and sexual perversion.

Neurasthenia is a disease most often found in hospitals in its uncomplicated form, but often accompanied by other morbid conditions which mask its symptoms, rendering diagnosis difficult. During the writer's connection with Mount Hope Retreat and also in private practice he has had the opportunity of observing a considerable number of cases, and he attempts in this paper to give a symptomatic picture of the disease for the benefit of the general practitioner, who is usually the first consulted by the patient. The treatment by the general practitioner is usually entirely symptomatic, consisting of bromides in increasing doses with the addition of hypnotics, the various coal-tar products and headache powders, with little or no effort to treat the underlying condition; the patient becomes worse or fails to improve, finally consulting a specialist or entering an institution.

These patients usually come from the city, though, perhaps, if the statistics of the relation of cases to the population from which they are drawn were obtainable, it would be found that there was little or no difference; many of the cases I have met with being farmers and country business men. In practically all cases, however, the disease affects those who work with their brains, and it is very rare indeed to observe it in the laboring classes, suggesting that want of physical exercise is a factor in its etiology. The disease appears in adult life, rarely in youth and probably never in children. In my experience there has been probably a greater proportion of cases among women than men, but this probably is incidental to the nature of the practice.

There are certain principal symptoms, or, better, stigmata, of the disease, some psychical, some physical,—a knowledge of which is necessary for a diagnosis.

Headache exists in about 90 per cent. of all cases, which has the peculiarity that it is at its worst in the morning, gradually decreasing as the day advances and disappearing at night, only to recommence the following morning; during the day there are usually slight ameliorations of the pain, especially at meal time, increasing again as digestion advances. The pain is a heavy, dull, numb feeling in the head, with perhaps occasional lancinating pains or paroxysms of intense agony. The decrease of the pain at meal time is of short duration, when digestion is at its height the pain is increased, accompanied by flushings of the face, giving the appearance of plethora, with a feeling of intense malaise and depression. Toward evening the headache declines; usually there is a severe attack after the evening meal, after which it may disappear entirely during the night, as long as the patient keeps the recumbent position; but on standing up it returns and in the morning commences again.

The headache is either bitemporal, surrounding the head like a vice, or more often it is in the occipital region, the whole of the back of the head to the nape of the neck having the sensation of a grinding or crackling, which may be so intense that the patient imagines he can feel the sensation with his hand. At other times the whole head is affected; the skull may feel too small for its contents; at others there is a sensation as if the brain were boiling; the forehead is flushed, giving a sensation of heat to the hand, the body temperature being normal, or nearly so.

* British Medical Journal, June 15, 1901.
† British Medical Journal, Feb. 3, 1900.

Though the headache ceases or lessens at night, the patient suffers from insomnia, which may be of two kinds. In one he falls into profound heavy sleep immediately on lying down, only to awake in two or three hours to spend the rest of the night in tossing about till morning, the victim of a thousand miserable sensations, turning from side to side from a feeling of discomfort, especially in the lower limbs, of shooting pains, prickling, stinging and general teasing sensations, followed by a feeling of numbness which is almost unbearable. He may doze for a short while at last, but is compelled to rise tired and unrefreshed, the headache returning as soon as he puts his feet to the floor. Should he doze for a few minutes the arm under the body becomes numb, paralyzed, dead; in a minute or two the sensation disappears, but the condition is renewed and he takes all sorts of uncomfortable positions to avoid its repetition, effectually dispelling any tendency to sleep; at other times the lower limbs appear to have a sort of shock or sudden contraction which is very disquieting. Other cases complain of a feeling of emptiness in the epigastrium, with gurglings in the intestines, more particularly marked toward morning. Urination is often frequent during the night, suggesting Bright's disease or diabetes, but there is no sugar in the urine and only traces of nucleo albumin are present. Under the above conditions sleep is evidently impossible, though toward morning he may pass into a doze or sleep for a short time, but is shortly compelled to rise as tired and miserable as when he went to bed.

The other form of insomnia differs from the above in that immediately after the evening meal he has apparently an almost uncontrollable desire to sleep, but once in bed he is wide awake, the entire night being spent in short snatches of semi-unconsciousness, he hears the clock strike every hour; the least noise seems to his tired senses magnified one hundredfold; the pressure of the bedclothes irritates him and he passes the whole night without any sleep which is of benefit to him. It is evident that the patient can have no desire for his daily vocations, the headache commencing as soon as he gets up and the day of misery and *ennui* repeats itself. Another peculiarity is that as the patient is dropping off to sleep he awakes with a sudden start and his rest is disturbed by "night terrors," delusions, and a feeling of dread.

Another symptom is a vertigo presenting special characteristics. It is not like the vertigo of Ménière's disease where there is a true loss of equilibrium and the patient falls—it is a sensation of emptiness of the head, accompanied by a weakness of the limbs; a cloud comes before the eyes, all appears gray with black moving spots, objects near and far are confused and seem to be on the same plane. These phenomena resemble accommodative asthenopia, which often coexists with vertigo; examination of the eye reveals little or nothing; the pupils may be dilated, usually equal in size, reacting a little slowly to light and the retina is normal. These attacks of vertigo are most apt to occur on the patient rising from the recumbent or sitting, to the erect position, or when any emotion is evoked, however slight. A form of agoraphobia may exist, the patient being afraid to walk along the street or to pass through a door, for fear the walls will fall upon him or an open space may produce intense sensations of fear. The vertigo shows itself most often in the morning, and like other symptoms it is less frequent during and immediately after meals, generally disappearing in the evening and never occurring in bed.

In some cases there are pains in the spinal column, either in the cervical or at the junction of the lumbar sacral vertibræ. The pains radiate in the former case toward the shoulders and arms, causing a sensation of weight and oppression; in the latter case the same feelings are experienced in the lower limbs. The patient locates the pain in the column exactly but examination reveals nothing, except perhaps a slight hyperasthesia; there may be sensations of feebleness and numbness suggesting paraplegia, but the sphincters are normal; the reflexes may be normal and equal on both sides, though exaggeration is not infrequent. The headaches and vertigo suggest organic brain trouble, the pains and symptoms from the cord suggest spinal trouble, and mental depression, insanity; and careful analysis of the clinical symptoms is necessary to form a correct diagnosis.

The stomach and intestines are also more or less affected in neurasthenia, suggesting auto-intoxication; there are a slowness and difficulty of digestion; on rising the tongue is coated, the mouth sticky, and the appetite poor; during eating and immediately after, the painful sensations are milder or they may disappear altogether —the general condition improving. A light breakfast is usually well digested, but it is necessary that another light meal be taken in an hour or two, or the patient will suffer. The condition of the stomach is one of continuous secretion of hydrochloric acid with a want of motility; it is therefore necessary that the neurasthenic be fed frequently at short intervals and on no account should he eat a large meal; although the hydrochloric acid is being continuously secreted in small quantities the glands are in a state of fatigue, and are therefore unable to respond to a demand for the excess of hydrochloric acid necessary for a large meal. After a test-meal the analyses give various results; usually the amount of free and loosely combined hydrochloric acid is normal or slightly low, though at times there is a marked hyperchlorhydria. The test-meal is never a very satisfactory method of diagnosis in a nervous patient. In the first place, the Salzer meal is not very appetizing and is more than the patient cares to eat, consequently the "psychic juice" is not secreted in full amount. The Ewald breakfast is not appetizing, especially with American bread; in Germany the "Brödchen" is much more pleasant to the palate, which may have something to do with the larger amount of free hydro-

chloric normally found in that country. To give a nervous patient a test-meal at 8 A.M., another at noon, and to draw his stomach at 1 P.M., during which time he is on a mental rack as to the terrible ordeal he is about to go through with the tube, is not calculated to produce normal digestion and give accurate results.

Judging from the urinary analyses in these cases one would consider that there was a marked hyperchlorhydria, and I believe that there are cases where not only the secretion is continuous to a greater or less degree, but that on taking a full meal there is a hypersecretion of hydrochloric acid which prevents proper peptic, and also retards pancreatic, digestion. In many cases the digestive symptoms are secondary to the nervous trouble, though careful attention to the diet and digestive organs mitigates the suffering, especially the insomnia. It is evident that no disease can be treated successfully unless the nutrition is normal, the absorption of partially digested proteids or imperfectly converted sugars cannot but be detrimental to the general condition. Tympanites and acid eructations follow a heavy meal consequent on the general atony of both the stomach and intestines, producing a certain amount of auto-intoxication, but the pathologic condition of the nervous system is often primary, the digestive symptoms disappearing as the patient improves. The intestinal troubles consist usually in obstinate constipation with occasional attacks of diarrhea in which, on microscopic examination, there will be found blocks of mucus, evidence of membranous enteritis, a very common accompaniment of neurasthenia. In women there is often a mucomembranous dysmenorrhea. The general condition of the patient suffers, he loses flesh rapidly, though in some cases the "embonpoint" is preserved.

The urine is clear, limpid and large in quantity, suggesting hysteria, though at times it may be less abundant and dark in color. The urea nitrogen is low, the ammonia and uric acid normal, but the residual nitrogen is markedly excessive, and there is usually a marked phosphoturia; the proportion of chlorides to nitrogen is below normal, while the carbon nitrogen factor is normal or low. Indol and ethereal sulphates may be high or normal, depending on the condition of the bowels, but the neutral sulphur is invariably high.

The heart suffers with the other organs; the maximum pressure is low in proportion to the mean and extremely variable. Under normal conditions the taking of food raises the mean pressure, but in neurasthenia so marked is the arteriolar contraction of the abdominal vessels, that an intense flushing of the face takes place, with a feeling of congestion of the brain and a beating of the cephalic arteries. At other times, owing to the relaxation of the abdominal vessels, there is an accumulation of blood in the abdomen causing a general sensation of cold; the hands and feet being, however, generally cold. To a great extent the vertigos are due to the same cause. On taking the erect position from the recumbent, there is under normal conditions, a rise of arterial mean pressure of about 10 mm. Hg. and a slight increase of the pulse rate; in the neurasthenic on the contrary, there is a fall of mean blood pressure on taking the erect position, of from 20 to 30 mm. Hg. and a very marked compensatory increase of the heart rate, which is insufficient to overcome the want or arteriolar contraction, and an anemia of the brain is the consequence, producing a vertigo for a few minutes till the arteriolar contraction takes place, when the vertigo passes off; in other words, the compensatory vasoconstrictor mechanism necessary for the erect position is deficient, reacting slowly to the stimulation of standing up.

The physiology of the blood pressure has been but recently investigated, since Leonard Hill and Bernard introduced their sphygmometer, it being the only one which will record both the maximum and mean pressures; the Riva-Rocci instrument usually used in this country is of little use clinically, as it only records the maximum pressure, and owing to its depending upon the sense of touch of the operator, the results are usually too low. Oliver and Hill have shown that any mental work or emotion raises the mean blood pressure, and it follows that continuous mental strain must produce a strain upon the vasomotor nerves, which results in their enfeeblement; and further, Sir William Broadbent has shown that continued mental strain produces a dilatation of the heart, the result of the continuous increased back pressure upon the ventricle. The effect of mental strain in the causation of neurasthenia will be referred to later, but enough has been said to show that primarily the neurasthenic condition is the result of a decreased sensibility or accommodative power of the vasomotor system.

Angina of a special type is common in neurasthenia; there is little precordial anxiety, nor are there painful radiations to the left arm; the thorax seems as though it were held in a vise; the pulse instead of being, as in true angina, small, thready and intermittent, is full and regular; the heart-beats are strong, even violent; the sounds distinct. Sometimes there is hyperasthesia in the precordial region resembling somewhat the condition found in hysteria, though the attacks of this angina are severe there is no danger of collapse. There is also a shortness of breath, oxygen hunger, the patient sighing frequently.

The functions of the genital organs are depressed, loss of power and desire are frequent causes of complaint. Coitus may be possible, but is followed by a feeling of intense lassitude with increase of pain in the lumbar sacral region. More rarely the patient is troubled with nocturnal erections which coitus does not relieve, sometimes accompanied by emissions, increasing the weakness and mental depression. At other times coitus is incomplete, ejaculation following almost immediately an erection. These symptoms suggest disease of the cord. In other cases, each defecation if followed by an emission of a thin fluid containing spermatozoa; in this condition

the prostate and vesicles should be examined for abscess and the discharge stained for gonococci. The writer treated a case which appeared to be a typical case of neurasthenia without headache, which recovered completely on the treatment of the prostate for a gonorrheal abscess; the spermatorrhea is due to atony of the seminal vesicles and can be cured by cold douches in the rectum. Cases with the above symptoms have been classed as sexual neurasthenia, melancholia being a marked psychic symptom.

Another symptom, which, however, is rarely present, is a certain amount of tremor usually slight, vibratory, affecting at the same time both the upper and lower extremities; the tongue is very rarely affected, but there may be a tremor of the lips causing difficulties of speech which suggest paresis.

The mental condition presents a general depression of the faculties without perversion; usually the mental activity is increased, sometimes decreased; intellectual work becomes difficult and above all the inability of the patient to make a decision on any matter however trivial; the memory, though slow, is intact and the judgment normal. With an effort, the patient is usually able to recover his mental aptitude completely, differing in this from the true melancholic in whom there are mental perversions, and from the paretic who has more or less lost control of his ideas. The neurasthenic will describe his mental condition exactly and the psychic depression from which he suffers without any impossibilities, exaggerations or delusions, with the exception that he has an exaggerated view of the severity of his case, with the idea that he is going insane, and that he will never recover. Restlessness is often a marked feature, the patient being unable to remain in one position or to sit still for but a minute or two at a time. Irritability of temper in some cases is very marked, the patient breaking out into uncontrollable fits of temper on slight provocation, perhaps swearing and breaking the furniture, resembling acute mania. Timidity may be a very marked symptom.

Constitutional neurasthenia is another form of the disease, according to Charcot and other writers, but the symptoms are the same, the subjects being those who are either congenitally or from some acquired condition less able to bear the mental and nervous strain of the struggle for existence, and who, therefore, more easily succumb to the strain of life. I do not believe that the pressure of modern civilization is greater than in former years; if more work is accomplished, more responsibilities carried by the individual than formerly, it must be remembered that the advantages of modern methods and appliances render such efforts more easy; and besides if the working strain is greater, the opportunities for diversion and recreation are also greater than formerly. There is perhaps one condition in modern life which tends to produce nervous and physical breakdown, and that is, that to-day the large majority of business men take but little exercise. Our forefathers either had to walk or ride horseback or drive; in the latter case the time consumed on a journey was longer than in these days of express trains and was to a great extent a rest from business cares, combined with a change of scene and environment which could not but be beneficial to the overworked man. We however, see men to-day who have led active business lives for half a century or more, hale and hearty at eighty years of age, and again we see men whose responsibilities have been light and whose anxieties have been few, succumb to neurasthenia.

In the so-called constitutional neurasthenia the clinical history reveals but little toward the etiology of the case; as an example, a young man of thirty comes to the office with many of the symptoms detailed above; in his history is neither hereditary alcoholism nor syphilis—those ever-ready refuges for the perplexed diagnostician; he may never have had any severe illness, and possibly the ordinary diseases of childhood have been so mild as to have almost escaped his recollection; he is possessed of a private income which renders him free from the anxieties of working for a living, and is perhaps working in some office more to employ his time than for ordinary pecuniary gain.

There is one point, however, in many of these cases which shows the cause of the neurasthenic condition, viz., that puberty was delayed, that he ceased to grow at the age of about sixteen or seventeen; that he was backward mentally, not perhaps as calculated from the standard of the school, but rather in his psychic development, associating with boys younger than himself, finding amusement in boyish or childish games. At about eighteen or nineteen the average boy becomes a man; he puts away childish and boyish things; but in this case he has remained a boy till perhaps twenty or even longer. In women, in whom this form of neurasthenia is more common than in men, menstruation may not have commenced till eighteen or nineteen years of age, and always been more or less scanty and irregular. The genitalia of the male are often small and poorly developed, and there has never been much sexual desire. Such cases are not true neurasthenia; they may belong to the class of cases known to the French as "type Loraine," or they may be cases of infantilism where the thyroid has failed to develop fully or has atrophied early; or they may be cases of anangioplasia.* The mean blood pressure is high; the arteries feel hard and small, suggesting arteriosclerosis, the heart rapid and forcible. These cases do not belong to neurasthenia properly speaking; their etiology being very different and consequently their treatment also. The prognosis of perfect recovery is, however, not good; the symptoms may be ameliorated but the patient will probably spend the rest of his life under the care of a physician, dying at a comparatively early age from some inter-

* See "The Thyroid and Parathyroid Glands." Williams Wilkins & Co., Baltimore.

current disease, owing to the reduced resistive power of the system.

True neurasthenia is found among those men who lead strenuous lives, having great responsibilities and anxieties without taking a sufficient amount of recreation and physical exercise, combined with irregular and bolted meals. The importance of the digestive apparatus cannot be overestimated, its complications render it liable to get out of order; consider that the saliva, the pepsin, hydrochloric acid, enterokinase, pancreatic juice with its three ferments, the bile, the succus entericus and other ferments, which are as yet but imperfectly understood, have all to secrete sufficiently and in proportion in order to convert the food into the condition in which it is most easily absorbed and assimilated, and that if any links in this chain are omitted, the nutrition will suffer, not only from decreased assimilation, but also from the absorption of imperfectly digested food products which must act as poisons to the system.

The etiology of neurasthenia can be classed under four heads: (1) Mental strain; (2) disturbances of digestion, malnutrition and auto-intoxication; (3) toxemia from infectious diseases; (4) traumatism and shock.

It is a matter of general knowledge that emotions affect the digestion, anxiety and grief cause loss of appetite, coated tongue, constipation, etc., producing malnutrition and auto-intoxication, which in their turn act upon the already overstrained nervous system. In many cases of neurasthenia the digestive disturbances antedate the nervous symptoms; in others the nervous symptoms are the first to appear, the one reacting upon the other in a vicious cycle.

Toxemia from grip, scarlet fever, diphtheria and other diseases sometimes leaves the patient a nervous wreck. Traumatism and shock are a cause of the same condition as seen in those nervous troubles dating from railway accidents, etc.

It is apparently the vasomotor nervous system which is principally affected. All emotions act upon this system of nerves. Leonard Hill has shown how mental work raises the mean blood pressure 30 to 40 mm. Hg.; if the nervous mechanism is continually under a severe strain for months or years, it is evident that it will become fatigued and refuse to react normally to stimuli. I have observed that there is a reversed postural blood pressure in neurasthenics, under normal conditions on taking the erect position from the recumbent, the mean blood pressure rises from 10 to 30 mm. Hg, while in neurasthenics, under the same conditions, there is a marked fall, sometimes as much as 40 mm. Hg, with a great increase in the pulse rate, showing that the vasomotor system fails to respond to normal stimuli. In neurasthenia the blood pressure is variable and erratic, falling suddenly when it would normally rise producing vertigo; at other times rising excessively, causing flushing of the head and neck, while the hands and feet may be cold. The vasomotor system regulates the blood supply to the various organs and it seems probable that many of the nervous symptoms classified as separate diseases are due to a defect of the vasomotor nerves controlling the blood supply to some particular portion of the nervous system, the variations in the symptoms depending upon the part affected.

There is yet another etiological factor which is of great importance from a therapeutic standpoint, viz., a gouty constitution. In these cases the urine is intensely acid and the carbon nitrogen factor very low. The most marked symptom is irritability of temper, sometimes so great as to resemble an attack of acute mania.

There is no specific treatment in neurasthenia. Removal of the cause of worry, if possible, increased physical exercise, anything to interest the patient in some form of recreation, attention to the digestion, to the removal of the toxins from the system and to the building up of the whole system in every possible way. Drugs, such as the bromides, the coal-tar derivatives, etc., should be used as little as possible on account of their effect upon the assimilation, the circulation and the blood; the coal-tar preparations are particularly contraindicated on account of their destructive action on the red corpuscles. Bromides depress the heart and the vasomotor system and should be used with caution. The difficulties of the physician are much increased by the intractability of the patient; he will refuse to leave his business or perhaps he is unable to do so; he will not take his treatment regularly, will absent himself from the office for a week or two at a time, returning perhaps to scold the physician because he is no better, or perhaps he will seek a new doctor every month; it is no uncommon occurrence to have a patient produce a pocketful of prescriptions from different physicians, upon all of which he will dilate with a curious mixture of astuteness and perverted knowledge, which would be amusing if it were not tedious. The first duty of the physician is to gain the patient's confidence, and by firmness and sympathy hold him to his treatment, a task often of great difficulty, requiring great tact and patience.

THE THEATRICAL PROFESSION AS A FACTOR IN THE DISSEMINATION OF DISEASE.

BY S. H. BROWN, M.D.,
OF PHILADELPHIA.

Much has been written during recent years concerning the various factors that exert an influence in the dissemination of disease but, as yet, nothing has been produced to show any relationship between the theatrical profession and certain forms of disease. In order to command attention for this subject one has but to ask consideration for two facts; first, the already undisputed fact of the causation of diseases by bacteria, and second, the migratory tendencies of Thespians as a class.

While the relation between bacteriology and disease is always of great interest its discussion may be conveniently omitted from this disserta-

tion on account of its extensive scope. It must, however, be remembered that while special bacteria may be found associated with a number of diseases, there is a marked inability to detect specific microorganisms in those that are most contagious, such as syphilis and smallpox, and it is the purpose of this article to bring out the clinical features of some of these affections as modified by the mode of life peculiar to the actor.

The habits and mode of life of those who follow the stage for a livelihood are subject to very great variations. For convenience, actors may be considered as successful and non-successful. Success in this profession may be considered from the standpoint of money or of art. Those whose success is monetary in character are least likely to diffuse morbid conditions throughout a community. Such individuals are able to procure all the comforts and accommodation possible, both in the large and small cities and towns; and in the event of illness, temporary or permanent, are also able to procure the best medical attention. But even with these advantages, the recognition and prompt treatment of certain affections are unavoidably postponed on account of the exigencies of the professional life.

Considering those successful as regards the theatrical art, the question becomes more intricate. The monetary success of these individuals is, with but few exceptions, periodic in character, all illness is cheerfully disregarded unless it had a direct influence upon the display of their talents and during the period of "hard times" everything is disregarded out of necessity.

These two classes should be instructed as regards their bodily conditions for their own sakes, while the other class yet to be considered should be the subject of constant attention on account of the influence they exert upon society in general.

The unsuccessful class is made up of failures as regards art and finance and constitute by far the large part of the theatrical profession. From the very beginning of their career, the members of this class often possess tendencies detrimental to themselves, their profession, and to society. Cleanliness as practised by other members of society is a dark mystery to many of these individuals. This mystery is allowed to deepen by lack of accommodations in the music halls, cheap theatres, boarding houses, etc., in which most of their lives are spent. Coupled with this are alcoholism and immorality, both of which tend to exaggerate the original unhygienic tendencies. While the effects of these influences are most marked in this class, they are by no means limited to it but permeate the upper strata, becoming greatly modified by the three great factors, intelligence, education and financial success.

The various sources from which the unsuccessful class is recruited differ but little in their several aspects from the positions they occupy in the theatrical profession so that in these cases, heredity and environment exert but a negative influence in the betterment of these individuals as a class. To dilate further upon this subject would be superfluous as their characteristics and tendencies are well-known to all.

The disease to which the various members of this profession are subject next claim our attention and at a glance it may be seen that these are the same in both cases, modified of course by the varying financial conditions from time to time. These affections may be conveniently considered as those that are regarded and those that are disregarded. The abnormal conditions that are regarded with alarm are usually those referable to the nose and the throat and the reason for this is obvious, considering the effect such conditions have upon the voice and therefore upon the patient's vocation. These conditions always receive prompt and efficient treatment from the best specialists in the various towns and cities, but after that, the physical condition is entirely disregarded.

The threatical profession is extremely large and its members occupy a considerable portion of their time in the performance of near work by their eyes and subsequent exposure to intense light, but how many of its members take the time to have their eyes properly examined and placed at rest and yet eye-strain is a well-recognized condition. Apart from this, the effect of cosmetics is seldom seriously considered, as the members of this profession may be frequently seen upon the street and in public places, with the same paint, powder, etc., as upon the stage. The pores of the skin, the innumerable openings of the ducts of the glands of the integument are forever closed up by these foreign substances and excretion is retarded to a corresponding degree.

The entire skin surface is seldom considered to the height of its importance. Full bathing is practised frequently by the upper class, but among the lower class, in addition to the not uncommon natural aversion to soap and water, there is frequently an inability to procure this priceless luxury. But this does not lessen the importance of its necessity. We are all familiar with the manner in which most actors and actresses die. The newspapers always attribute it to immorality and alcoholism, but considering other branches of society we shall find an equal degree of immorality and alcoholism but a longer average term of life due undoubtedly to the observance of the every-day rules of personal hygiene known to all and considered by all except the theatrical profession. Looking over the lives of those members who have survived to rather old age, this is proven with great force.

The skin, as is well known, takes part to a large extent in the excretion of the waste products of the body and the blocking up of the avenues of escape in this structure by cosmetics, sweat, sunburn, etc., can have but one effect, namely to increase the work of the other organs of excretion.

The infectious fevers, such as smallpox and diphtheria, occurring in these individuals probably receives greater attention than from other classes

of society. Vaccination is well understood and accepted more extensively than by the outside public. With diphtheria, the recognition and treatment are prompt for the reasons already stated. Scarlet fever is comparatively infrequent among the members of this profession but the possibility of large epidemics should always be taken into consideration. Typhoid fever, on the hand, is rather common. Hard work, improper hygiene, dissipation, poverty, etc., all aid in its production and unless the patients can be removed to a hospital or other quarter appropriate for their care, the diffusion of the disease is certain. The mild types are particularly dangerous in this respect on account of the ability of the patients to follow their respective troupes from place to place.

More frequent than the infectious fevers in this class are the parasitic disease of the skin. Most of these are secondary to lack of bathing, wearing of unclean and contaminated clothing, and exposure to variations in the dermal temperature. Perhaps the most common affection of the skin encountered in travelers and others whose place of residence is continually changing is scabies or itch. This is essentially an animal parasite disease and is acquired by contact. While not attended by danger to life the affection is extremely aggravating and shows no tendency to undergo spontaneous involution. Medical works describe it as a disease induced by the presence of a minute parasite, *Sarcoptes scabiei*, beneath the skin. The parasite burrows its way through the skin leaving its ova in its trail. This produces intense itching which is worse at night and causes the patient to scratch considerably, thereby producing a multiform eruption upon the skin made up largely of scratchmarks, pustules, etc. It selects certain regions of the body by preference, namely those places where the skin is warm, moist and thin, such as the webs of the fingers, the wrist, the flexor surface of the elbows, the armpits, the female breasts, buttocks, shaft of penis, inner side of thighs, legs and ankles, and between the toes. The itch-mite and its burrows may be detected in any of these situations and is considered diagnostic. In a typical case it is not difficult to detect all these characteristics but typical cases seem to restrict themselves to the dirtiest of people. However, there is very little to prevent these individuals from infecting others, since the affection respects no class and usually those with typical cases are outcasts and receive no attention from themselves or anyone else.

Mounting the scale, the condition undergoes many variations depending on the tendencies of those affected. For instance, in those who subject their hands, arms, and forearms to repeated washings, the disease may be largely eradicated from these surfaces or at least the itch-mite and its burrows may be entirely removed from these situations yet the patient suffers from intolerable nocturnal itchings and continues to infect those about him. This leads to failure of recognition of the condition by the average practitioner of medicine on account of the absence of the burrow which he has been taught to regard as the sole distinguishing feature of the disease. As a further result these atypical cases are ascribed to the uric acid diathesis, etc., and treated accordingly, but without success. It should never be forgotten that the face is free in scabies except occasionally in nursing infants.

The possibility of dissemination of this disease is enormous when the constant changing of costumes, and the huddling together in railway trains, cheap hotels, boarding houses, etc., are considered. Not only do members of the same troupe become infected, but others following and occupying the same apartments (often without a change of bed-linen) become the subjects of this affection, differing according to the habits of the individual, but possessing in all the one prominent feature of intense itching at night. Obviously the underclothing and bed-clothing should be boiled in all these cases in addition to the medical treatment. The affection is also acquired during sexual intercourse, but this is ignored almost universally, and in mild localized forms it may be confused with more serious affections.

Another condition to which the theatrical profession is exposed is that of pediculosis of lousiness. When we consider the number of young women with long hair that go to make up the larger part of the numerous traveling troupes and the facilities they have for keeping the head in a perfect condition, the possibilities are enormous. *Pediculosis capitis* is therefore extremely frequent and is made more so by the various headwear employed and the means provided for its transportation.

Luckily, a number of these women bleach their hair and, unknowingly, antisepticize their heads. The prominent constituent of most hair-bleaches is peroxide of hydrogen and this exercises a solvent effect upon the gelatinous capsules of the ova or nits attached to the individual hairs. Apart from the intolerable itching and discomfort attendant upon pediculosis in all forms, there is exerted a deleterious influence upon the general health and most such individuals become pale and anemic; the hair becomes lusterless; and the adjacent glands enlarge and sometimes suppurate.

Pediculosis corporis demands attention, since the presence of an individual so affected may give rise to endless trouble and annoyance through the infection of the clothes of other members of the same troupe as the parasite lays its ova in the seams of the clothing and hatches them out under the influence of heat. This explains the occurrence of itching in this affection only when the clothes are worn and directly after removing them.

Itching is alike in all diseases of the skin and the scratching induced by one is no different from that produced by another so that these individuals present themselves with lesions upon the skin that differ, apparently at least, in no way from those of scabies or itch. Physicians often refuse to entertain the thought of pediculosis in cleanly individuals and make a hasty diagnosis of eczema

but herein lies the danger as eczema is non-contagious. To the experienced observer, however, the difference is apparent; the itching and scratching is almost invariably situated on the outer side of the arms, thighs, and legs, the backs of the shoulders, and areas corresponding to the seams of the clothing. The hands, feet and face are free and there are no burrows as in scabies or primary lesions as in eczema.

Pediculosis pubis, commonly known as "crabs" occurs with great frequency in the pubic region and is usually associated with unclean sexual intercourse, but it is not always acquired in this manner. The clothing may be the medium of contagion in this as in other diseases. As is also well known these parasites may be found in the armpits, eyebrows and eyelashes, giving rise to inflammations of the skin, the true origin of which may be overlooked by the casual observer. The common practice of rubbing in blue ointment in this affection is to be deprecated as in careless hands its use may lead to dermatitis or ptyalism and equally beneficial results may be obtained by less harsh modes of treatment.

The vegetable parasitic diseases of the skin may be dismissed with passing mention, for while they are contagious, they produce little or no disturbance. Their greatest importance lies in ease with which they may be confounded with more serious affections. For instance, the macular eruption of syphilis may resemble *Tinea versicolor* or choasma and again the circinate lesions of late secondary syphilis may be considered as ringworm. The microscope serves to render the diagnosis certain in these cases.

Passing from the parasitic affection of the skin, our attention is next directed toward venereal diseases, the contagiousness and manner of acquisition of which are common knowledge. These affections, however, are rendered more virulent and their contagiousness increased by the mode of life of the professional actor, particularly those of the lower class and appear in aberrant forms that elude detection by the patient and also occasionally by the physician.

Syphilis is a frequent affection in this class of individuals and while it is usually acquired during sexual intercourse, it may arise from contact in other ways. The chancre or initial lesion may occur in situations in which it is difficult to detect although it is usually situated on the external genitals. The appearance of the secondary eruption, especially the roseola, may remain undiscovered and the disease pass rapidly into the tertiary stage. The mucous patch often remains alone for a considerable period and when we consider its location in the mucous membrane of the mouth, rectum, and genitals, the ease with which the disease is disseminated becomes at once apparent. Then, again, the patient disfigures these lesions by the application of caustics and other irritants by the advice of friends or charlatans so that even a skilled physician may be deceived. The moist papules that occur between the folds of the buttocks in syphilis usually remain untouched by reason of their not being exposed to view and are especially characteristic.

The tertiary lesions of syphilis, being looked upon as non-contagious by the medical profession, may be disregarded as far as dissemination of disease is concerned but should receive proper attention for the patient's sake. These lesions are usually seen in the more successful members of the theatrical profession because these individuals manage to survive the many vicissitudes of their calling. The gumma, when external, is easily recognized but the tubercular and papulotubercular lesions are often confused with other affections of the skin and grave internal manifestations of the disease are allowed to occur. The tendency of the papulotubercular lesions to form incomplete rings should never be forgotten as it will often serve to render the diagnosis clear.

The treatment in these cases is often attended by great difficulty. As in all other syphilitic persons there is a tendency to discontinue treatment as soon as the lesions begin to disappear and herein lies the great danger. Medicine should always be taken for a period of two or three years, under the supervision of a physician. The ingestion of drugs during that period does not constitute the entire treatment; the patient should be seen by the physician from time to time and the treatment varied. In the event of the patient being unable to pay for treatment, he should be directed to the proper hospital or dispensary, but how many are so instructed? Most frequently they consult quacks, or drug store "doctors" and after four of five months' treatment depart, apparently cured, to return with some late lesion or die at a comparatively early age from internal lesions. In the meantime, how many individuals within and without the theatrical profession have acquired the disease?

Chancroids are probably less frequent than the previously described affection and on account of their easy recognition are promptly treated. By the laity nearly all lesions of the genitalia are considered as chancres and are almost invariably cauterized. In the event of the lesions being chancroids, the result is beneficial but if the lesion is a chancre, the treatment has been useless and harmful in that it served to mask the real condition.

Gonorrhea is probably the most frequent disease and its causes are obvious. The underpaid condition and immorality of the lower classes tend to propagate this affection with great vigor. Coupled with this is the lack of opportunities and, likewise, desire for personal cleanliness. Gonorrhea in women seems to last indefinitely, even when all the conditions are favorable for its eradication on account of the numerous folds and crypts of the genitalia in which the infection lodges. How much more so must this be in those who are deprived of the privilege of taking proper care of themselves either by reason of straitened financial circumstances or lack of proper accommodations.

The secretions from such individuals carry in-

fection and must certainly contaminate the clothing. While this may probably be the least potential factor in the dissemination of this disease, it should always be remembered. Gonorrheal ophthalmia, with its frightful sequences, should likewise never be forgotten when considering the possibilities attending the diffusion of this affection. While the sequences of gonorrhea are not directly pertinent to this subject it is difficult to dismiss it without alluding to the fact that sterility in both sexes is traceable in a large percentage of cases to it. Blindness in children in many cases and a large number of abdominal operations are also its results.

In conclusion it may be well to summarize the facts contained within this paper as follows:

1. That the theatrical profession is a factor of great importance in the dissemination of scabies, pediculosis, syphilis and gonorrhea, by reason of its peculiar sociological position.

2. That this influence is greater in traveling troupes than in companies located permanently in the large cities on account of the lack of accommodations and unhygienic conditions under which they live.

3. Living apart from the rest of the world as they do to a great extent they are deprived of the medical education which is becoming so popular with the rest of the laity.

4. Lack of time prevents the members of this profession from consulting able medical men in the large cities except when physically incapacitated and in consequence they fall into the hands of unscrupulous and ignorant physicians or charlatans.

The relief for this series of evils is not easily produced. Probably the best means of preventing the spread of these affections would be by educating the members of this profession in the various dangers attending these conditions. While the first two parasitic affections are not dangerous the are extremely annoying and inconvenient and may be readily prevented and cured. Facilities for frequent bathing should be provided in the boarding-houses and the accommodations at the theaters should be such that the lesser lights could properly care for themselves. The manner in which the costumes are handled cannot be too harshly condemned. With the resurrection of old costumes for a revival of any kind, it is scarcely less than miraculous that all the diseases known to man are not equally distributed throughout the company. The sterilization of these costumes at least once would do no material damage and would greatly aid in lessening the danger of transmission of disease. Because an individual is upon the stage it does not necessarily follow that he or she should be entitled to the diseases already mentioned, and, further than this, the outside public should be protected, as it is said many succumb to the wiles of the "merry merry."

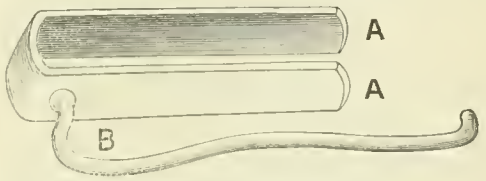
INSTRUMENT HANGER FOR GLASS-SHELVED CASES.*

BY FREDERIC GRIFFITH, M.D.,
OF NEW YORK,
SURGEON, FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

Last summer, during a visit to the private operating room of Mr. Hurry Fenwick, of London, I noticed in his instrument case a device which appeared to me would be a valuable addition to glass-shelved instrument cases. Forgetfulness upon my part prevented me from learning whether that gentleman was himself the inventor or not. The invention consists of a hook for suspending hemostats, scissors and many other like instruments which, when spread out over the shelves, occupy needless space. The copy of the model which I have made is of brass.



The straps (AA) are made from a strip of moderately springy metal seven-sixteenths of an inch wide and one-sixteenth in thickness. The length of the straps are 2¾ inches. The thickness of my shelves vary from three-eighths of an inch to seven-sixteenths of an inch and the spread of the straps has therefore been made with these measurements in view, so that moderately firm pressure is made above and below the shelf when in position. The hook (B) is made from wire three-sixteenths of an inch in diameter and 4½ inches long, being soldered to the strap as in illustration, after having been bent into shape. The implement is placed in position either from the front or back of the shelf.

49 East Sixty-fourth Street.

FORENSIC EYE ASPECTS OF TABES.

BY JAS. G. KIERNAN, M.D.,
OF CHICAGO.

While neurologists and clinicians lay stress on the Argyll-Robertson pupil in the differential diagnosis of locomotor ataxia, yet it, like most pathognomonic symptoms, exceptionally occurs in many conditions. Differential diagnosis here as elsewhere is but too often a pedagogic performance unsuited for actual practice in which atypic not typic cases furnish the main necessity for diagnosis. The Argyll-Robertson type of reflex iridoplegia is associated with preserved accommodative mobility where the pupil is as immovable as a frozen opening, no matter how brightly illuminated or how deeply shaded, but contracts when the finger is approached to the nose. It has been temporarily noted after railroad accidents and other shocks, in cases in which no subsequent evidence of grave neuroses had occurred. In such cases it disappears. Excep-

*Presented at the Academy, Surgical Section, December 4, 1903.

tionally it has been found in alcoholism. It occurs early in locomotor ataxia, in paretic dementia, in constitutional syphilis. However, constitutional syphilis occurs quite frequently in which it is absent.

As W. L. Baum* has said, the frequency of the Argyll-Robertson pupil in constitutional syphilis is overrated. That it is frequent in parasyphiloses like paretic dementia and locomotor ataxia is undeniable. It is not to be received as a pathognomonic mark of these conditions, since it has been found in conditions like alcoholism and therefore may be a temporary expression of toxic states occurring during constitutional syphilis.

Some years ago I was called to testify in a suit against the Chicago Union Traction Company in which the driver of a mail wagon who had served as a soldier during the Civil War and had died of tuberculosis ere the case in litigation came to issue. His mail wagon had been struck by a car of the Chicago Union Traction Company and he was thrown from the seat. Fourteen days after this accident a diagnosis was made of locomotor ataxia, chargeable to traumatism, from an alleged condition of the pupils of which no clear description was given in the testimony. The diagnostician (a member of the family) who had observed the pupils under very disadvantageous conditions seemed to have some idea, as far as could be gathered from his testimony, that there was reflex iridoplegia of the Argyll-Robertson pupil type.

In response to a hypothetical case based on these facts I testified that in my judgment locomotor ataxia due to the traumatism did not exist and that diagnosis from the eye symptoms alone was not justifiable. Had locomotor ataxia existed there must have been symptoms of its presence before the alleged accident. It might even, from the destruction of coordination, have contributed to the accident since, unless in a remission, a tabetic has not the necessary coordinating power for a driver in city streets.

This issue was not raised by the company, albeit the declaration specified locomotor ataxia. In their defense to personal injury suits, corporations rarely plead a prior state of ill health on the part of the plaintiff. They accept the claim agent theory of pure fraud, thus raising an issue which any attorney with legal acumen is ready to meet despite jury and judge fixing, hospital staff packing and other corporation guards against the wicked wiles of alleged "ambulance chasers."

As the preponderance of proof element is always strongly in favor of the defendant corporation, as this preponderance extends to the issue of contributory negligence, and as any morbid condition where occupational ability is impaired makes for contributory negligence, the lobbyist is shown in the fact that he forces the defense of pure fraud in cases where occupational ability is damaged by ill health existing prior to the accident. The same evil influence appears in the denial of symptoms of permanent injury where such symptoms really exist but are chargeable to pre-accident morbid states.

MEDICAL PROGRESS.

MEDICINE.

Transmission of Tuberculosis from Man to Cattle.—The present investigation is complementary to one published by the same authors several years ago on the relation of bovine tuberculosis to man. The work considers the following questions: (1) Whether the tubercle bacilli found in primary tuberculosis of the intestinal canal in man are ordinarily virulent for cattle, and (2) what is the frequency of primary tuberculous infection of the intestinal canal in man. Special attention has also been paid to the tracing of the infection through the agency of milk. The authors, J. Fibiger and C. O. Jensen (Berl. klin. Woch., Feb. 15, 1904) inoculated a series of calves with pure cultures of tubercle bacilli taken from patients afflicted with primary intestinal tuberculosis. Out of 10 cases, one-half produced only a weak reaction or were practically avirulent, the remainder resulted in a marked virulent reaction. In only one-half the cases therefore was a progressive tuberculous infection noted in the inoculated calves. It is also noteworthy that among five cases of apparently primary intestinal tuberculosis in children, four produced bacilli which were particularly virulent for cattle. Cases such as these, where no other modes of infection seem possible, where primary intestinal tuberculosis and bacilli virulent for cattle are present, and where the children have been fed on raw milk taken from uncontrolled herds, show conclusively the necessity for insisting on proper precautionary hygienic measures. Koch has said that extreme precautions against intestinal infection are unnecessary, as such cases are comparatively rare in man. The authors have made careful autopsy records in a series of 213 cases examined in a period of two years, and among 116, in which tuberculosis was the principal disease, 13 were afflicted with primary tuberculosis of the intestinal canal. This is approximately about 6 per cent. of all necropsies and about 11 per cent. of all those suffering from tuberculosis.

Bronchoscopy for Foreign Bodies in the Bronchi.—The diagnosis of these has largely rested on the history of swallowing some object and the subsequent cough, pain, and, rarely, localized physical signs, especially the signs of a simple small area of consolidation. Then came the radiograph, exceedingly useful where the foreign body is of metal or some other substance opaque to the rays, but of no value for a nut or a plumstone or anything that will not throw a sharp shadow. But now, according to Lermoyez and Guisez (La Presse Médicale, Dec. 23, 1903), one has in bronchoscopy an efficient method of absolutely detecting anything in any of the larger bronchi, for not only can the tube be passed to the tracheal bifurcation, but owing to the elasticity of the lungs may command all the larger bronchial ramifications. For treatment the medical man would resort to emetics, turning the patient head down and slapping his back, etc., and if these failed adopted an expectant attitude hoping that the object would be either coughed up or extruded through a fistula. Bourdillat found the death rate in spontaneous evacuation through a fistula to be 56 per cent. Surgeons by low tracheotomy reduced the mortality to 30 per cent., sometimes doing much harm by blindly

poking instruments into the bronchi. Transmediastinal bronchotomy has been tried with a death rate of 100 per cent. But the authors believe that bronchoscopy is harmless and easy to perform, and has the advantage that on making the diagnosis the foreign body can be at once easily extracted. They report the successful extraction of a nail, which could be located by X-rays, but which there seemed no possible way to get at.

Amœbæ Dysenteriæ.—Dysentery, according to the latest researches, would seem to be either *bacillary* due to bacteria, or *amebic* due to *Amœbæ dysenteriæ,* or *mixed,* that is, ameho-bacillary. The amebic are more common in hot than in temperate climates. The symptomatology of the two varieties is very similar, the differential diagnosis being made certain only by examination or cultures of the stools or serum reaction. But the amebic type tends to be chronic, is characterized by alternating exacerbations and periods of apparent health, and is sometimes complicated with abscess of the liver. The bacillary type, on the contrary, is sudden in its onset, runs an acute course, and recovery or death results in fifteen or twenty days. The amebic stools are generally alkaline, the bacillary neutral or acid. Anatomically the amebic lesions are confined to the large intestine, but the ulcerations are deep with overhanging edges. The bacillary lesions may appear not only throughout the whole large intestine, but also in the ileum, and the necrosis is superficial, never reaching the muscular layer. H. Vincent (La Presse Médicale, Dec. 23, 1903) reports a case of amebic dysentery, which, after a serious course and various kinds of treatment, including antidysenteric serum, finally yielded to ipecac, calomel and opium. In studying the case the serum reaction was negative, and the stools were loaded with round, ovoid or pear-shaped amebæ of about four or five times the diameter of a red blood corpuscle. These amebæ held as inclusions red blood cells, cellular fragments and bacteria, thus distinguishing them from the non-pathogenic *Amœbæ intestinalis vulgaris,* and the pathogenic *Amœbæ coli mitis,* neither of which engulf red cells. The ameboid movements were free, the hyaline portion of the protoplasm alone forming pseudopods. The nucleus remained always of the same shape. At the temperature of the laboratory the movements were very marked for ten to thirty minutes, or in some cases for an hour. Then they gradually became slower and finally the parasite took a spherical shape with a prominent nucleus. At no time was a contractile vacuole seen. While living, the amebæ cling to the slide, but as soon as dead are washed off by the currents in the water. Shortly after the movements have ceased the differentiation between the ento- and the ectoplasm disappears and the parasites may be taken for epithelial cells. Contrary to the opinion of Ucke, the author has found in a number of cases, that the serous liquid on the surface of the stools contains amebæ in almost as great numbers as the mucus or blood, and that they are more motile. Urine inhibits the movements. To observe these the cover-glass must be lightly applied, and motion may be stimulated by lightly tapping the cover-glass with a fine wire or by brusquely alternating light and shadow. Following a dose of calomel, the stool contained many less hematophagic amebæ. They were mostly smaller (20 μ), and motionless, and on the third or fourth day a great many of them had no nucleus, their protoplasm was either hyaline or uniformly turbid, and they were spherical with intensified outline. A few of them had a double wall, the encysted form. Fixation by any of the common fixing reagents was not followed by successful staining (the amebæ stain better when hardened in the tissues), so a drop of aqueous methylene blue was placed on the living organisms, while all the other elements of the stool are stained blue, the amebæ remain uncolored and prominent. After about ten minutes they take on a spherical form, but soon throw out pseudopodia which keep up a constant motion. After six or eight minutes the pseudopodia cease and begin to imbibe the color, which attacks first the ingested cells, débris and bacteria. After ten minutes more the nucleus becomes colored and death ensues, and then the whole organism takes the stain. By this same method, the effect of other agents was tried. Silver nitrate, osmic acid and mercuric bichloride were followed by rapid death. Potassium permanganate is less active. Tartaric, citric and oxalic acids immobilize and soon kill; tannic acid is very active. Picric acid is mild, and boric acid and weak alkaline solutions have no effect. But of all the substance tried, the most certain and most energetic was the neutral hydrochlorate of quinine. The amœbæ retracted instantly, seemed to disappear, then became clumped and unrecognizable. This salt would seem therefore to be very useful in the treatment of dysentery, while methylene blue, which is so much used, is one of the least efficient remedies.

SURGERY.

Treatment of Cervical Adenitis.—One of the most important points in the treatment of this condition is considered by F. S. Bulkeley (Am. Med., Feb. 27, 1904) to the care in avoiding or minimizing the amount of scar. The method which is usually mentioned plans the incision to take advantage of the natural skin creases. The writer thinks that in many cases it is possible to go still further. He divides the cases into three classes: (1) Cases in which the severity of the symptoms or the location of the infection is a menace to life and active interference is called for; (2) tuberculous glands; (3) where immediate radical interference is not demanded. The first class of cases occur relatively seldom and the question of a secondary scar becomes of secondary importance. In the case of tuberculous glands early treatment is of the greatest importance, and he recommends radical excision where improvement does not soon follow medical treatment. He emphasizes particularly the treatment of the third class of cases. The condition of the channels which they drain should be carefully looked after. Where suppuration has taken place, he suggests aspiration of the pus with the subsequent injection of antiseptics, or the use of a seton. For injection a solution of dioxide of hydrogen (50 per cent.) with or without the addition of iodine was followed by the best results. Where this is too painful or cannot be done, a cotton or silk seton may be used and the thread moved several times daily. Drainage may be hastened by the application of a hot poultice. Neither of these methods should be resorted to in the case of deep cervical glands.

Deceptive Abdominal Signs.—Our knowledge of the indications for operation, while vastly improved, are as yet of infantile development. A. H. Tubby (Brit. Med. Jour., Feb. 13, 1904) states that unfortunately it must still be admitted that the only method of positively settling the diagnosis is to make an exploratory incision; but this is only another formula for acknowledging defeat. It at once takes the case out of the realm of science and places its treatment simply among the lower arts. Some of the conditions which render a diagnosis of the utmost difficulty are as follows: In many abdominal lesions the symptoms for a time are absolutely latent, only becoming recognizable when they are of such severity as to make intervention hopeless. On the other hand, certain cases which commence acutely, subside and apparently are

progressing favorably when of a sudden they break out with increased virulence and end fatally, the latent period having utterly deceived the clinician. Again, when the general symptoms of suppuration are present, it is sometimes impossible to say with which organ it is connected, and no data are present upon which to commence exploratory investigation. There are certain symptoms which cannot be too frequently brought before the observation of all practising physicians. In the order of their importance, they are as follows: (1) The ratio of the pulse to the temperature. If these are proportionate, the outlook is favorable, but a rise of pulse with a fall of temperature is a condition of the utmost gravity. (2) Leucocytosis. Although this sign is of the very greatest importance, it is not absolutely to be relied upon by any means, for the greatest and most acute forms of poisoning are not attended with any elevation. The ratio of polymorphonuclear cells is important. If these are increased from the normal rate of 65 per cent. to from 70 to 75 per cent., pus formation is certainly present. (3) Rigidity. This, even in the absence of other abdominal signs, is of the utmost value. (4) Vomiting. This is a variable sign, although most acute abdominal conditions commence with it. It is often absent in the latent period. If it recurs after the stomach has been emptied, it becomes of important significance. (5) Distention. This is not a characteristic sign of the early stages and may be absent even in intestinal perforation. In later stages, its vital significance is well known. If it persists longer than twenty-four hours, it is of grave moment. (6) Constipation and diarrhea. The former may be due to obstruction or to sedatives, but the latter is often indicative of septic absorption from a closed abscess. (7) Local tenderness. (8) Hematemesis and melena. (9) Increasing abdominal dulness. This, after a serious injury, is indicative of hemorrhagic effusion.

Surgical Treatment of Gall-stones.—The almost universal presence of inflammation in the gall-passages as an etiological factor in gall-stone cases is now generally admitted. The infection may reach the gall-bladder by ascending the ducts from the duodenum, by penetrating the walls of the bladder—by way of the blood vessels. Stones are very rarely formed in the ducts, those which are found there having originated in the bladder. B. F. Curtis (N. Y. Med. Jour., Jan. 2, 1904) believes that expectant treatment should not be persisted in to the extent which has been thought allowable in the past on account of the danger of serious inflammatory processes. A grave cholecystitis with perforation is only too common and on account of the absence of jaundice the connection with the biliary system is not recognized. Appendicitis is frequently the diagnosis, especially when the gall-bladder is low down. The colicky pain, localized tenderness and rigidity over the gall-bladder are the principal signs and operation should be done if the symptoms are violent or if they do not soon abate. Obstruction of the common duct is often allowed to persist for weeks or months, at the expense of the patient's welfare, for cholemia is dangerous and so is the exhaustion of the patient from suffering, fever, and limited diet. Hepatic cirrhosis and interstitial nephritis are frequent accompaniments of persistent cholemia. Calculi in the bladder or cystic duct may also demand surgical interference. The usual symptoms are pain in the epigastrium, sometimes radiating, more or less nausea, vomiting, febrile disturbance, with or without leucocytosis, abdominal tenderness, especially over gall-bladder, and rigidity of right rectus muscle. Jaundice is sometimes present as a result of inflammation of the ducts or more likely due to pressure from the stone lying in the duct or the pressure of the distended bladder itself. If the symptoms persist unaltered for a time (two or three days in the severe cases, a week in the milder ones), there is serious danger of gangrene or perforation of the bladder, peritonitis or other grave septic complications. The special signs of danger are increasing rigidity of the muscles and an increasing leucocytosis, frequent blood examinations being made. The pulse, temperature, nausea and vomiting are less important signs. Even if the stone passes the chances are that more stones are present in the bladder and give rise to various "digestive" disturbances. He believes that the advantages of operation while the stones still remain in the gall-bladder or cystic duct and before grave infection has occurred are numerous: (1) Any inflammatory condition can be improved or cured just as drainage cures urinary cystitis; (2) Consequences of obstruction of the common duct are avoided; (3) Further attacks of cystitis and colic are prevented; (4) Further calculus formation is prevented, for the bladder may be removed or rendered so healthy by drainage that no more calculi will form; (5) The dangers of cholecystitis, chronic pancreatitis and cancer of the gall-bladder are much diminished.

THERAPEUTICS.

The Medical Treatment of Neuralgia.—The most effective medicinal agents in combating this condition have undoubtedly been the various coal-tar antipyretics, all of which have in addition an antineuralgic action. E. Meyer (Berl. klin. Woch., Feb. 8, 1904) highly recommends hydrochinon as a substitute for the antineuralgics ordinarily employed, but at the same time urges the use in addition of the physical measures of treatment. The drug is given in increasing doses, from 1 gram to 4 grams in twenty-four hours, in solution. The preferable time for administration is at night as the patient retires. The solution should be freshly made and kept away from the light. Marked perspiration is frequently seen, especially on the affected limb, but no unpleasant after effects were noted except in one case where nausea and vertigo were present. He does not claim that it affords a cure for these cases but believes that it is a very efficient palliative remedy.

Determining the Strength of Digitalis Leaves.—The only safe way to insure a uniform strength of digitalis leaves is the physiological test, according to C. Focke (Arch. d. Pharmacie, Vol. 241, No. 9). Frogs of the species of *Rana temporaria*, caught between the end of June and the end of September, are treated with subcutaneous injections of a 10 per cent. infusion until the proper dose is found which will bring about a permanent contraction of the exposed cardiac muscle in from seven to twenty minutes. An arbitrary value is then determined by dividing the weight of the animal by the dose multiplied by the time. The loss in strength depends chiefly upon age and insufficient drying; it is therefore best to dry the leaves until they can be readily powdered. They should be kept in this condition in air-tight jars and will then retain their potency for a long time. Estimating the percentage of digitoxin is absolutely useless since an almost inert drug may contain as much glycosides as a very active one. Parallel analyses made by two different chemists showed that there is no relation between the results of the chemical and the physiological tests. This is best explained by the fact that certain extractives and other glycosides enable the digitoxin to dissolve readily in water; under the influence of moisture these bodies are probably destroyed, so that the digitoxin is left.

SATURDAY, MARCH 19, 1904.

THE LUNGS OF NEW YORK.

A movement has recently been on foot to preempt parts of certain parks in crowded portions of New York city for the purpose of erecting on them temporary school buildings in which those children who cannot now find accommodation or only incomplete accommodation in our present school buildings may find places. This movement is distinctly reactionary and the suggestion is one that is fraught with danger to present health and with risks for the future.

These parks have been obtained in many cases only after strenuous efforts on the part of those who are unselfishly trying to make life more livable for the poor. It is now well known and is generally unrecognized that the death rate of any portion of a large city depends to no inconsiderable extent on the amount of breathing space allowed the inhabitants. The parks that are situated in the midst of crowded districts are simply invaluable institutions for the saving of lives. They have been well called the breathing spaces of the great social body "the lungs of the city." It would be unfortunate to diminish this influence for good in any way and the adoption of this suggestion with regard to schools would certainly do so.

Education is an extremely important element in life, but it is not nearly so important as health. There are among the medical profession not a few who consider that children are rather harmed than helped by the strenuous methods and constant application demanded of them by modern educational systems. There is no doubt that there may easily be an overanxiety in this matter. There are many children who would know more at fifteen if they had not been stunted in physical, and consequently intellectual, development by unseasonable application to books between seven and ten.

The present movement seems, to some extent at least, to be a political move. There was a promise that sittings should be found for the nearly 80,000 children who are at present without complete facilities for attending school and now even questionable means may be employed to fulfil pre-election promises. This would be unfortunate. Any resumption of the park space already acquired for any other purpose than that it now fulfils would almost surely serve as a precedent in such cases and might lead to the feeling that this sort of thing could be done time and again whenever there seemed to be any special need for it. The reasons might not always be even so good as they are at present, when they are doubtful enough.

The excellent work that has been accomplished by the retiring Tenement House Commissioner and the methods he introduced into his department might thus to some extent be easily nullified. At the present time, instead of the old, awful dumbbell tenement houses, mainly composed of dark rooms, sanitary, comfortable and decent houses, even when intended for many families, are being rapidly built all over the city. Instead of the old, heavy, fetid air which prevailed in the tenement-house district, whenever one crossed the threshold, as many a young doctor in practice has good occasion to know, there is excellent ventilation in these new houses. Instead of windows opening in close proximity to the windows of adjoining houses, no window now opens within twelve feet of the window opposite and more often they are twenty-five feet apart. The air shaft is gone, as it should have gone many years ago. This is paying attention to the lungs of the great city body politic from another standpoint and already it has accomplished a noteworthy reduction in the mortality in crowded districts. It is improvements like this and those that have been secured in the small park system that must by all

means be maintained if the new administration is to have the confidence of New York citizens.

Physicians are naturally more interested in these matters than the rest of the community. It behooves the medical profession then to use its influence wherever possible for the conservation of present gain with the hope of securing still further advances in the city's sanitation. On these two subjects the preservation of our parks and the maintenance of the tenement-house law, with the enforcement of all its important regulations, physicians must concern themselves.

The present administration has given every sign of a sincere desire to accomplish the duties imposed upon it in every department. Let us hope that in these grave questions of the public health there shall be no derogation from the high standards that have been set by the old Departments of Health and of Tenement Houses, but on the contrary, that we shall have what is the only guarantee of the substantial maintenance of what has been gained up to the present, the further progress that will assure the continued amelioration even of our present satisfactory hopeful conditions.

"AS THROUGH A GLASS—DARKLY."

The tenth annual report of the Craig Colony for Epileptics, which has been lately issued, is a most valuable document, and one which should reflect great credit upon the managers and officers of the institution at Sonyea.

One of the principal items of interest in this pamphlet, to the medical observer at least, is the report of the Craig-Spratling gun, which seems to have exploded a bursting shell into the theory that epilepsy is not infrequently caused by the eye strain, resulting from refractive errors, the correction of which, it has been maintained, would cure the disease.

Whatever the progress of modern ophthalmology may have been, its most strenuous upholders and most ardent admirers cannot deny that its standing in the general profession, among its sister specialties, and even in the laity itself, has been most seriously injured, if not irreparably impaired, by the extravagant eulogies of yet untested procedures and the utterly fallacious hopes of cures, that have been loudly heralded by certain men.

To such an extent have these methods been advertised, and written up, by their originators and their disciples, that a long-suffering and disappointed public, weary of a failure that would be classed in a business community as "non-delivery of the goods," have risen in their wrath and have mentally consigned the "eye strain" of the ophthalmologist,—with the "brain fag" of the neurologist,—to the limbo of the "refraction parlor" of the shop-keeping optician, and to the columns of the testimonials of the cure of nervous diseases, in the daily newspapers. There is not an ophthalmic surgeon in the country who has not, in the last ten years, exerted all the skill at his command in his efforts to undo the unhappy results of ill-advised tenotomies, and now, according to this report of Dr. W. P. Spratling, the use of glasses has proved to be anything but an unmixed blessing to the epileptics at Craig Colony.

As a nation, we Americans have lived a rapid and energetic life, and if it is true, that some of us have a skeleton in our nursery closets, we can hardly expect that its bones will not rattle to the music that was piped to our ancestors, in the days when men preferred Port wine to sarsaparilla, and women loved not only widely, but too well. The sins of the father are apt to be visited on the children, to the third and fourth generation, and the epileptic inheritance is hardly one that can be discounted by the cylindric glass of fashion, or the prismatic mold of form. No one can doubt the efficacy of glasses in certain cases, or question their absolute necessity, but their adaptation has not, as yet, driven all other remedial measures from the field, and we are still skeptical as to their power to reduce a congenital dislocation of the hip, or their ability to control an epidemic of yellow fever. And yet, we *are* asked to believe, that their prescription will modify, if not remove, one of the most serious and deeply rooted ills, that human flesh is heir to.

And now let us turn to these two reports, and compare the happy and rosy fancies of the first, with the sad and lead-colored facts of the second. On page 46 Dr. Spratling states as follows under the heading of "Eye Strain and Epilepsy":

"Dr. Geo. M. Gould, of Philadelphia, has long been of the opinion that epilepsy is not infrequently caused by eye strain, the relief of which would cure the disease. In my last annual report reference was made to the work of Drs. Gould and Bennett in carefully examining and fitting 68 patients at the Colony with glasses. We quote from the report referred to in part as follows:

"'The preliminary report of this work published by Drs. Gould and Bennett in *American Medicine* for September 18, last, is full of interest. Among other things the report states:

"'The astonishing fact, and one that we think deserves most serious attention, is the enormous propor-

tion among these patients of cases of injurious astigmatic and anisometropic defects. Sixty-seven of 68 had astigmatism and it is noteworthy that about one-half of the entire number of patients had unsymmetric astigmatism, a defect which almost invariably produces the most injurious results upon cerebral and assimilative function. . . . We do not say that these high and most injurious ametropic defects caused the epilepsies of these patients; that can only be determined in future by the careful records of seizures to be kept and compared with those of the past.'

"If there is anything of value in the treatment of epilepsy along this line, we are anxious to know it, and all patients so carefully fitted with glasses by Drs. Gould and Bennett, are being especially observed so that in a year or so we may make comparisons of their seizures before they wear glasses and after."

This arrangement strikes us as a most fair and impartial method of testing any virtue that may lie in the correction of refractive defects, for the relief of eye strain, producing epileptic seizures. The experiment was to be made at Sonyea, where the environment and opportunities were better adapted for such tests than in any other place in this country, and the glasses were to be fitted—if not by the originators—at least by the upholders and defenders of the faith. Medicine is proverbially a conservative science, and we can hardly expect the general practitioner to abandon his time-hallowed armamentarium, for what our Western colleagues have flippantly and disrespectfully alluded to "as a self-advertised, warranted not to rub off, blown-in-the-glass, method of cure." Certainly not, at least, until its claims have a firmer foundation than the mere *ipse dixits* of a few visionary enthusiasts.

That this caution was not unnecessary is farther shown by Dr. Spratling, who goes on to say (after a year's trial) in regard to the result of the adaptation of glasses:

"We regret having to report disappointing results. The table that follows shows that one patient only out of the 68 experienced any benefit in his disease while wearing glasses. This man's attacks were usually severe and were preceded by a definite bilateral motor aura. His mental condition was unimproved, and he has now gone ten months without a seizure. He had four attacks in October and four in November, after being fitted with glasses late in August, 1902."

The table referred to is full of interest, particularly in regard to Case X of the male and Case XI of the female list. In both of these the number of seizures were reported as 0 in the three months preceding the prescription of glasses and yet, in each the number of attacks increased to a grand total of nine in the succeeding half year. Now, it is a poor rule that will not work both ways, in medicine as in anything else, and if, as Dr. Gould states, it is true that an uncorrected astigmatism will produce an eye strain that may in turn result in epilepsy, how does he account for the increase in the morbid symptoms in these two cases, which appears to be concomitant with the installation of compensating glasses? It is a perfectly evident fact, that the placing of a cylindric lens of any number, before an emmetropic eye, will produce an artificial astigmatism, which will of course correspond to the strength of the glass employed, and, under other hands it is possible that such a glass might have been used when it was not indicated. As, however, the glasses were fitted by Drs. Gould and Bennett in person, it can only be explained on the ground of the increase of some exciting condition, which the glasses were unable to control, and which in itself is a confession of weakness in the theory, and an indication of failure in its action.

That Dr. Gould may not regard it in this light, and that he may rejoice more over the one ewe lamb that was saved, than he will sorrow over the sixty-six cases that fell by the wayside, seems probable ,as his only remark on the results, when brought to his notice, was: "The unsatisfactory results do not affect the fundamental fact that in a certain proportion of cases the cause, or a contributing cause, may be, and is, eye strain. The results at Craig Colony, I suspect, are due to the fact that in chronic cases and under the conditions, cure is not to be expected. Even in the younger patients, the constant attention of the oculist and of optician is requisite, and this could not be supplied at the Colony.

"I have had one case of typical grand mal in private practice, free now from attacks for four years; the cure due to relief of eye strain. In general, however, the result of the test at Craig Colony re-emphasizes the old truth that the cure of epilepsy consists in its prevention. If proper glasses could be given as a preventive measure in young epileptics, and the care of oculist and optician insured, I have no doubt that epilepsy could be warded off in a certain proportion of cases."

Now, what Dr. Gould may mean, by the *"constant"* attention of the oculist and optician we do not know. We have heard of ambitious students of foreign tongues, who "slept with their dictionaries," but we have never considered it essential that epileptic patients should either breakfast with their oculists or sup with their opticians. These particular patients were carefully fitted to

glasses by the men most interested in the results, and, as the report says, that they were under the *daily* care of one of the staff of the Colony, it does seem as if all the necessary requirements had been fulfilled.

The whole truth of the matter is, that we have, from a neurological standpoint, given a most undue and unwarranted prominence to the ills that the errors of refraction are capable of producing, and have then placed an almost fanatical and child-like confidence in the power of glasses to relieve them.

We have not only tested the eyes of the living, but we have ruthlessly investigated the post-mortuary murmurs of the past, and have even invaded the cold *hic jacets* of the dead. We have been taught that King Arthur should have been treated by Merlin for "brain fag"—that the chronically acquired diplopia of Brian Boru ought to have been relieved by prisms, and that the Epistle to the Corinthians was curtailed by the *migraine* of St. Paul, which was due, probably, to latent hypermetropia, uncorrected by convex glasses. Unfortunately all these illustrious personages have long since passed away, and their testimony is no more available than was the evidence of the Texan horse thief, that was hanged first and then tried afterward.

These theories, however, are all merely scientific toys—the pleasing musings of an idle hour. At the best, they are useless to the practical physician and their virtues may be summed up in the trite and classical criticism of a previous generation: "there is much in the world that is both new and true, but unfortunately those things that are new, are not true, and those things that are true are not new."

PHARMACY AND MEDICINE.

At the seventy-fifth annual meeting of the College of Pharmacy of the City of New York, held last Tuesday evening, a unanimous affirmative vote was cast for the ratification of the amalgamation of the College of Pharmacy with Columbia University, the former to represent the pharmaceutical faculty in the University development.

This step is one of much importance not only to the many pharmaceutical interests of this city and country but to the medical interests of the city as well.

It is now only about a hundred years since a pharmacist first isolated morphine from opium and opened the way to a great stream of investigation that has made modern pharmacology possible and the study of the physiological action of potent drugs effective. It may come as a painful surprise to many physicians that the greatest part of this work of investigation and discovery has been carried out not by the students of medicine but by pharmaceutical chemists and were it not for them we would still be dosing our patients with the nauseous draughts that were given by Paracelsus, Boerhaave, Sydenham and our medical forebears.

The investigation of active principles has been as keen and as strictly professional in its aims and enthusiasms as has been the search for changes in morphological structure in nerve and viscus. Out of the former have been created large commercial enterprises that have pushed forward and given to the profession not only practical standard and palatable pharmaceuticals but the great flood of newer synthetics without many of which the modern physician would be stripped of much of his power to comfort and to heal.

Pharmacy has often been called the handmaiden of medicine. In therapeutics, if the signs be read aright, we fear that the physician has wandered far from the paths of research, and is now the patient and blind follower of the more active, wide-awake and enterprising pharmaceutical chemist.

This, however, is but a swing of the pendulum and we hope that the lessons taught will have a salutary effect in awakening medical interests to the situation that confronts them. Behind the veil of commercialism, too thick at times it must be confessed, to be entitled to such a mild term, perfectly ethical investigations have been encouraged by the pharmaceutical interests in this and other lands, but many of us have been blinded to this development because of the commercialism that has placed pharmaceutical enterprises under an ethical ban.

In this amalgamation we see the development of a broad university ideal such as is found in our European centers. By it we witness the welding of the best interests of scientific pharmacy and practical medicine, and in the union of one of our oldest and best pharmaceutical colleges with New York's greatest university we can confidently hope to see the standards of pharmaceutical education raised to a level worthy of its professional heritage and to look forward to the time when the professional developments in pharmaceutical education will animate, govern and regulate the tradesman.

ECHOES AND NEWS.

NEW YORK.

Infectious Diseases in the Bronx.—An epidemic of measles and scarlet fever has broken out in the Bronx, and at the present time there are more than 400 cases of measles on record with the Bronx Board of Health and between 150 and 200 cases of scarlet fever, with a daily increase of cases. The Department of Health in the Bronx is crippled by the need of disinfectors, there being only four men to do this work. It is expected that additional funds will be provided this week.

New Scholarships for College of Physicians and Surgeons.—The Committee on Scholarships at Columbia has announced five Harsen scholarships for the next Academic year—two for the second year class, two for the third, and one for the fourth. Also eight Vanderbilt and Faculty annuities, to be awarded upon presentation of satisfactory evidence as to ability, class standing and moral character. Announcement of successful applicants will be made about July 1. Each scholarship will be worth $250, of which $125 is to be paid at the beginning of each half year. There are no gratuities provided for students of the first year.

Special Medical Courses at Teachers College.—Teachers College has announced a special course of lectures in connection with its regular work in physical education and its special one year's course, arranged at the request of the Society of Superintendents of Training Schools for Nurses for preparing trained nurses to become superintendents of hospitals and principals of training schools for nurses. Two lectures on the nervous system have already been given by Dr. S. E. Jelliffe. Two will be given by Dr. W. A. Bastedo, on materia medica, and methods of teaching it. Other similar lectures will follow.

Measles Return.—The record of cases of the past few weeks has convinced the officers of the Board of Health that the measles have struck town again in the more or less epidemic form which they seem to take every other year or so, which has given rise to the expression that "measles skip a year." There are at present 1,435 acute cases in the five boroughs, and the number of cases convalescent raise the list to over double that number. It is not possible to state positively how the present number of cases of measles compares with that of previous outbreaks, as figures have been approximately complete only in the past few years, but the present number exceeds that of any other year since 1898.

Mt. Sinai Attending Physicians.—In addition to the attending physicians mentioned in last week's Medical News, the following should be included: Attending Genito-urinary Surgeon, Dr. H. Goldenberg; Adjunct Attending Genito-urinary Surgeon, Dr. Martin W. Ware; Adjunct Attending Physician (Children), Dr. Henry Heiman; Pathologist, Dr. F. S. Mandlebaum; Assistant Pathologists, Dr. E. Libman, Dr. E. P. Bernstein, Dr. Herbert L. Celler; Anesthetists, Dr. M. L. Maduro, Dr. Myron P. Denton; Admitting Physician, Dr. Max Rosenberg.

The East Side Physicians' Association.—This Association held its first annual dinner at the Tuxedo, March 12. Dr. R. Abrahams presided. The following gentlemen responded to toasts: Dr. Ignatz Morvay Rottenberg, President of the Association, answered to the toast "Our Society;" Health Commissioner, Dr. Thomas Darlington, responded to "The Health Department and the Physician;" Prof. Richard James H. Gottheil dilated on "Medicine and Humor," and Mr. Carl Hauser humorously discussed the difference between the East Side and the West Side Physicians.

Watertown Epidemic Abating.—Dr. George A. Soper, of New York, the sanitary expert, who is in charge of the typhoid fever situation at Watertown, says that there is a marked improvement. The number of cases reported daily shows a decided decrease, and the total number of cases is much less. The number of cases now in the city is less than 500. Arrangements are practically completed for supplying the city with pure spring water. Some tank wagons will be run until the filtration plant is in operation next fall.

Proposed State Water and Sewer Commission.—A bill has been introduced at Albany which places the water and sewerage systems of all towns in the State under control of a Board of Management. This board has power to plan new sewerage and water plants, to provide for the extension and improvement of old plants, and to exercise legal control over all conditions detrimental to public health. The salary of each commissioner is placed at $8,000, a secretary will receive $3,500, a marshal $1,500, and the clerical force consisting of inspectors, bacteriologists, chemists, etc., will be the other officers. As the bill reads the commissions will "consist of three competent persons who shall be appointed by the Governor by and with the consent of the Senate for a term of five years. One shall be a competent civil and hydraulic engineer and one a competent sanitary engineer and bacteriologist." Nothing is said about the third, but if the measure goes through it is likely that a medical man will be appointed.

New York State Lunacy Report.—The fifteenth annual report of the State Commission in Lunacy was presented to the legislature last week. The total cost of maintaining the 24,187 insane in the State hospitals during the last year was $4,104,689, and the average weekly per capita cost was $3.32, an increase of twenty cents a week over the preceding year, or a gross addition to the maintenance fund of $382,342. In addition the commission expended $632,000 for new buildings and extraordinary improvements. Five thousand new cases of insanity developed during the year, or 434 more than during the previous year. There were 1,263 recoveries and 1,100 were also sufficiently improved by treatment to enable them to return to their homes. The percentage of recoveries was 24.72, as against 24.60 the preceding year. The total number of insane in all institutions was 25,934.

Immigrant Lunatics.—The commission reports a continued and increasing burden resulting from the admission to the institutions in and about New York City of alien lunatics. Notwithstanding increased inspection at Ellis Island and other ports of entry a considerable increase in the number of admissions of patients of this class was noticed during the year. Difficulty is experienced by the commission in returning these aliens at the expense of the steamship companies bringing them to this country because of inability to determine the antecedents of many of this class owing to their confused mental conditions. The commission refers to the constant increase in the number of old and demented cases in the State hospitals, and suggests as a possible relief to existing conditions the boarding out system of the insane in private families, now so successfully practised in the State of Massachusetts. The commis-

sion points out that if this system were adopted by the State, the closest inspection of the insane, even when cared for in their own families at a per capita rate to be allowed them, could be provided.

Colony Offshoots.—The commission directs attention to the latest development in the way of colony offshoots from the large State hospitals, namely, the fitting up and occupancy of the lake side cottage and accessory buildings in connection with the Rochester State Hospital. These buildings are located on the shore of Lake Ontario, several miles distant from the hospital, and during last summer large parties from the hospital were installed at the colony, the stay usually lasting some two or three weeks for each party, with resultant benefit to the patients. The most important development in this direction, however, will be the possible using of the old Sammis Hotel buildings, on Fire Island, now under charge of the Quarantine Department. The commission renews its recommendation for the establishment of a reception hospital in New York City designed for the immediate care and treatment of acute and curable cases of insanity; that arrangements be made at general hospitals in the larger cities and towns for the temporary detention of emergency cases, this provision supplanting the use of jails and station houses for this purpose; also the establishment of so-called convalescent houses at a distance from the hospitals for patients not sufficiently recovered to return home, yet able to leave the institution.

Immigration and Insanity.—A State board of expert sanity inspectors, to be stationed at Ellis Island, and to inspect immigrants with a view of detecting those in such stages of mental weakness as would lead to their becoming a public charge, is provided for in a bill to be introduced in behalf of the State Commission in Lunacy. Although immigration is wholly a national Government affair, it is said that the United States Commissioner of Immigration is in favor of the proposition for a State board, and that the necessary permission would be granted by the general Government. The interest of the State in the matter is conceded, as a large proportion of the mentally defective become charges upon the State within a short time. It is estimated that the expense under the proposed act would not exceed $25,000 a year, which would include one chief inspector at $5,000, two inspectors at $3,000, a male interpreter at $2,000, and a woman interpreter at $1,500 per year. It is said that the foreign-born inmates of the hospitals for the insane number more than 50 per cent. of the whole, and it is believed that the proposed inspectors, by their exclusion of mentally defective immigrants, would save all the cost of the board. The United States Marine Hospital has charge of this matter at present, but it does not employ experts in mental disease, and there is no means of detecting mental disease except through a physical manifestation of it. It is said by the chief officer of the New York City Pavilion for the Insane, that often insane patients are received who have been in the country only a few days or months. The city of New York has no local interest in the matter, as such patients become a State charge. In a letter on the subject, Commissioner of Immigration Williams says that whenever this proposed board should determine that an immigrant was insane at the time of his taking passage, he could be deported at the expense of the steamship company; and that if no such proof existed he could be deported at any time within two years at the expense of the Government. The proposed bill is said to be favored by Gov. Odell.

Mt. Sinai Hospital.—With impressive ceremonies and in the presence of the Governor of the State and other officials the new Mount Sinai Hospital was opened last Wednesday afternoon for work. One of the speakers, who has long been a friend of the institution, referred to the time when Mount Sinai was struggling to raise a $10,000 fund for the sake of continuing its mission, and he spoke with a glow of pride of what the charity had become. Occupying a whole block and comprising ten buildings, costing in all nearly $3,000,000, the Mount Sinai Hospital was revealed Wednesday as a monument to the generous impulses of those who had for many years labored to upbuild it. More than fifteen thousand persons had been bidden to the public reception and two-thirds of that number were present Wednesday afternoon and evening. The block from Fifth to Madison avenue and from One Hundred and First to One Hundred and Second street, which the buildings occupy, was guarded by platoons of police, who kept the throng moving to and from the doors. Sixty guides escorted parties of fifty visitors each through the buildings, for so many were the halls and corridors and wards that the guests might have become confused in the place and portions of the hospital would have become overcrowded. Governor Odell and former Lieutenant-Governor Woodruff, Charles V. Fornes, president of the Board of Aldermen, representing Mayor McClellan, and other prominent men arrived at one o'clock and were escorted to the directors' room. Isaac Wallach, president of the institution, made an address of welcome, after which the Rev. Dr. Samuel Schulman, rabbi of the Temple Beth-el, offered prayer. Mr. Joseph Fox, in the absence of Isaac Stern, chairman of the Building Committee, who is ill, presented the keys of the hospital to the directors. Governor Odell was then introduced: "I have been much interested in the work of enlarging Mount Sinai Hospital," said the Governor, "and I take this opportunity to congratulate you on your success. The work accomplished by such private institutions as this is one of unselfish interest. I have no doubt that in this hospital devoted to the alleviation of human suffering, which knows no creed or nationality, there will be found a field which will call for the greatest effort and sacrifice on your part. I have no doubt, because I know the generous impulses of your race, that whatever is demanded will be forthcoming."

Mr. Fornes praised the unselfish spirit which had called Mount Sinai Hospital into being.

Edward Lauterbach referred to the early struggles of the institution and to the success which had finally crowned its work. "There is a distressing spectacle in this city," said he, "and it is that kindred institutions are threatened with diminution in great services because of lack of funds. That condition can never come to Mount Sinai as long as the pulse of the great Hebrew community beats in unison with those of its directors, whose sacred duty it is to preserve and maintain it."

All of the visitors were deeply impressed by the size and convenience of the buildings. Although the structures are separate in appearance, they are in reality so connected by means of ground floor corridors that there is communication with all parts of the institution. The buildings are of pressed brick and limestone and are constructed in the most substantial manner. Five of them, the medical, surgical

and private hospitals and the children's and isolation pavilions, are for the housing of patients, and they contain in all 456 beds. Every possible detail has been followed out which will insure cleanliness and freedom from infection. There are no sharp corners or angles anywhere in the institution except in a few ornamental portions. The corners of the walls and the places where the floors and the walls join are rounded so that there are no angles in which dust may collect. Each building has an independent ventilating system, by which air drawn from high above the street level into the cellar is filtered and distributed through the building by means of large fans after it has been warmed to the desired temperature.

Typhoid at Poughkeepsie.—Within a few weeks many cases of typhoid fever have developed in that city, and new cases are being reported daily at Vassar Hospital, twenty-one patients now being treated for that disease. The situation is regarded so grave that last Wednesday a conservative local paper declared that the attention of the State Board of Health should be called to the epidemic, and that vigorous sanitary methods must be taken to wipe out the disease. It is further urged that the city authorities might wisely close every well and stop all sources of drinking supply except the city water, which latter is taken from the Hudson River and sand filtered.

Health Inspectors.—An excellent bill is now before the Assembly relative to the grading of Inspectors on the staff of the Board of Health of New York, which merits the support of public-spirited citizens. It amends the charter of New York by the addition of a section providing that on and after the first day of January, 1905, all Health Department Inspectors who have been for fifteen years in that work shall be classified in the first grade; those of ten and less than fifteen years' service in the second grade; those of from five to ten years' service in the third grade, and all of less than five years' service, including all who may hereafter be appointed, in the fourth grade. Continuous and faithful service will entitle an Inspector to be advanced from a lower grade to a higher one as he passes the five, ten, and fifteen year periods respectively. The pay of the several grades is fixed as follows: Fourth grade, $1,200 per annum; third grade, $1,500; second grade, $1,800; first grade, $2,100. These salaries are subject to such deductions for sickness, absence on vacation, fines, and forfeitures as the Board of Health shall prescribe by rules applicable to all grades alike. The work of the Health Department is a service of experts. It calls for special knowledge, and in no branch of the public work is experience more valuable. It is not to be expected that any one qualified to pass the civil service examination and undertake the duties of an Inspectorship can be had for less than $1,200 a year. He should be a physician or an engineer, and to secure promotion he must give up all opportunity for another career. If after five years he is not worth $1,500 he does not belong in the service; and if after fifteen years, by which time the average Inspector will have reached or passed forty, he cannot be sure of a salary of $2,100 at least, he has absolutely no incentive to make the work of the department more than a temporary convenience, to be abandoned as soon as any other opportunity is offered. Above all things, the faithful Inspector who attends to his duties and not to his "pull" must be protected against the injustice of remaining stationary in his position and salary while new men with more potent influence are appointed at higher salaries and put over him. The efficiency of the public sanitary administration depends upon the judgment and experience of our Health Inspectors. If they are inefficient or corrupt the Board of Health is powerless. The salary demands of the Inspectors are extremely moderate, and the principle for which they contend in urging the enactment of the bill referred to is too sound to permit discussion.—N. Y. *Times.*

PHILADELPHIA.

Typhoid Fever.—Though the typhoid fever cases for the past week were considerably less than during the preceding week, the disease is expected in almost epidemic form in the ensuing month. This is because of the exceedingly filthy water that has been supplied during the recent high freshets in the rivers. Filter beds are promised but seem to be still far in the future.

Pharmacist Examinations.—The report of the last examination of the State Pharmaceutical Examining Board shows a large percentage of failures to secure certificates. Of the 215 applicants for the certificate of registered pharmacist, only 136 qualified; of the 138 who sought to be qualified assistant, only 88 passed.

Medical Laboratories of the University of Pennsylvania.—At the dedication of these laboratories on June 10, many noted physicians will deliver addresses. Among the names already announced are those of Dr. H. P. Bowditch, of Harvard; Dr. R. H. Chittenden, of Yale; Dr. George Dock, of Ann Arbor; Dr. H. C. Wood, of the University of Pennsylvania. The general committee of arrangements will hold its first meeting on March 19. Many of the members of the American Medical Association, which meets at Atlantic City during this week, are expected to attend the exercises. The laboratories have been three years in building, the approximate cost being $700,000.

Filariasis.—At the meeting of the Pathological Society on March 10, Dr. D. Riesman showed for Dr. F. H. Howard, of Williamstown, Mass., the heart of a dog that contained numerous specimens of the *Filaria immitis*. In discussing the question of filariasis, Dr. Allen J. Smith advanced a hypothesis to explain the periodic appearance of the filaria embryos in the peripheral circulation. He believes that the phenomenon depends on the caliber of the peripheral blood vessels. During the daytime, or the period of the host's activity, the tonic contraction of these vessels do not permit the passage through them of the embryo parasites. During the period of rest the vessels relax sufficiently to allow the parasites to appear in them. This is believed to be possible without causing capillary embolism.

Acute Hemorrhagic Leucemia.—A case of this imperfectly understood condition was reported at the section on Medicine of the College of Physicians, March 14, by Drs. J. H. Musser, J. N. Wistar and N. B. Gwyn. The patient was a male, aged fifty-one years, with a good family and personal history. The disease began as a sore throat, the patient thinking he had taken cold. At about the same time hemorrhagic spots appeared on the forehead. A few days later one of the postauricular lymphnodes was found to be enlarged; this was followed by involvement of the postcervical nodes, the parotid, and submaxillary glands. There was bleeding from the gums and tonsils, with suffusions of blood over the chest and legs. The temperature rose as high as 103° F. The blood count showed red cells below

two million, leucocytes 382,000; the differential count gave 98 per cent. lymphocytes. Blood cultures were sterile. The patient died on the forty-fifth day of the disease.

Lorenz to Receive Degree from Jefferson.—It is announced that Dr. Adolph Lorenz will be present at the annual commencement of Jefferson Medical College in May to receive the honorary degree of Doctor of Laws. He is expected to take part in a clinic to be held at the hospital of the college a few days later, at which Dr. Albert Hoffa, of Berlin, will also be present and operate. Prominent English orthopedic surgeons are also to attend the clinic.

Free Hospital for Poor Consumptives.—At the annual meeting of the board of this institution March 14, President Lawrence F. Flick said there had been such a diminution in the amount of the donations received during the past year that the society had been compelled to cease maintaining thirty free beds in the hospitals of Philadelphia. These had been supported for several years for consumptives who for various reasons could not be cared for at the White Haven Sanitarium. Dr. Flick believes this drop in donations to be due to the erroneous impression that Mr. Phipps had also endowed the White Haven institution when he made his gift to Philadelphia. There is a waiting list of over 300 patients for the sanitarium. Dr. Flick recommends the establishment of a farm for convalescents where they can be employed at partially remunerative wages. Election of officers resulted in the reelection of Dr. Flick as President.

The Henry Phipps Institute.—The fifth lecture in the International Course, given under the auspices of the Phipps Institute, will be delivered by Prof. Eduardo Maragliano, of Genoa, Italy, on Monday, March 28, at the Witherspoon Bldg., Philadelphia; the subject being "The Specific Therapy of Tuberculosis and Vaccination against the Disease." The profession at large is invited to attend.

CHICAGO.

Hospitals Seek New Law.—The representatives of the various hospitals of the city met recently in the rooms of the Chicago Medical Society to discuss suggested changes in the city hospital ordinance, which is said to be so defective that, were it enforced, no hospital could operate under its provisions. After considerable discussion, a subcommittee was appointed to draft a new ordinance. The members of this committee are Drs. D. A. K. Steele, of the Chicago Hospital; L. Blake Baldwin, of the Samaritan Hospital; A. J. Ochsner, of Augustana Hospital; J. H. Hoelscher, of Alexian Brothers' Hospital, and M. L. Harris, of the Passavant Memorial Hospital.

Society and Criminals.—In an interview, published in the Chicago *Inter-Ocean*, March 6, Dr. G. Frank Lydston, among other things, says that the individual criminal is not responsible for his crime. Society itself is to blame for all the evils that exist in it. Under the present social system the degenerate classes—the criminals, insane, inebriates, and paupers—are increasing almost three times as fast as the population, which threatens to result in the degeneracy of the American people. The evils of society are the diseases of society. There is, then, a pathology of the social body, comprising most of the evils from which society suffers—crime, social evil, pauperisms, insanity in its sociological relation, anarchy, by which the author means destructiveness; political corruption, and disturbances incidental to economic and industrial activities. He contends that degeneracy underlies all social evils. Any marked retrogression in the scale of development constitutes degeneracy. These evidences of degeneracy are most often found in the crime class, for degeneracy constitutes the underlying cause of criminality. Any given social system has just about the proportion and kind of degenerates that it deserves. If Chicago is overrun with criminals, if it is filled with paupers, if it sends hundreds of insane to the public institutions, one may know that, from a scientific standpoint, it deserves them. The criminal is the microbe; the social environment is the soil that gives it growth. The human being is naturally vicious and criminal. This veneer of culture which has gathered through the ages keeps the average man from becoming criminal, but when vice and crime break out, it is simply the barking back to the primitive impulse. If there were no social scheme there would be no crime. Our prevailing crime and vices only begin at the initiation of the communal social state. Our social system begets the inebriates, the epileptics, the evil women, and the insane. They are merely the flotsam and jetsam of the social action. They are the evidences of society's self-contamination. This contamination begins at the marriage license window, for we never have had sense enough to govern matrimony. Matrimony should be run on the same lines as the life insurance business. Until it is, we will have the vicious and the criminal—and the divorce court. When men and women of degenerate tendencies marry, their children will be degenerates. Degenerate children mean thieves, murderers, evil women, paupers, insane, cripples, consumptives, epileptics, and inebriates. If we will control the issuance of the marriage license, confining it to people whom the State knows to be not degenerates, we will do away with much of our costly legal machinery, our asylums, our jails, and our almshouses. Punishment and reform along present lines are failures. It is true that some criminals have been reformed, but, in the aggregate, moral persuasion and punishment have shown no results. Despite all the punishment, crime has increased. While this condition exists, it would be folly to expect we can grow better or even hold our own. Crime is now increasing much more rapidly than the population. From 1850 to 1890—long periods must be considered in a question of this kind—the population of our country has increased 170 per cent.; while the number of our criminals increased 445 per cent. Criminality among females has greatly increased. Suicides have increased. In New York alone in the ten years, between 1886 and 1896, felonies increased 90 per cent. The startling increase in crime in American cities, while due in part to the stupidity of our government in permitting our country to be the dumping ground for the social refuse of Europe, is largely due to influences that are peculiarly American. The American thinks harder, works harder, and for longer hours, and takes less healthful recreation and rest, than any other man on the face of the globe. These conditions tend to favor a faulty, nervous constitution, and with this comes degeneracy and all its attendant evils.

Remedies.—The most efficient remedy would be the absolute prohibition of marriage among people of this class. Public sentiment is against it, but public sentiment favors parental consent, a demand for the age of the parties, and is against the marriage of blood relations. Inebriates should never be allowed to marry, for inebriety is the most important cause of degeneracy. The insane, the epileptic, the pauper, the criminal, or the incurable consumptive, should be denied the right to be married. It may be argued that such control of marriage would be interference with individual rights, but in everything else individual rights are submerged

in social rights. In making an immediate fight against these evils, the author would clean and purify every plague spot in the city. The slums breed the degenerates; society makes the slums. Morality and self-respect are incompatible with squalor, dirt and poverty. We do not find self-respecting people in the slums. He would have model tenements in which the bath would be a prominent feature, clubs for boys and girls, lectures, concerts, theatrical and educational entertainments, clean streets and alleys. This would go far to stem the tide. Free baths and gymnasia are far superior in his opinion to missionaries or civilizers in the slums. The cities may grow deplorably bad, be overrun by degenerates, be terrorized by criminals, be made poor by supporting its paupers and its disease, but the blood of the rural districts is what it must rely upon to keep it from ruin. If Chicago would spend in cleaning itself one-half what it spends for the punishment of people whose crimes are a result of its filthiness, these crimes would be greatly decreased in number. But the American cities largely refuse to do this, and the result is that there is an alarming increase in the number of vicious and criminal persons, and a natural tendency toward degeneracy.

Antitoxin for the Poor.—The City Health Department in its weekly Bulletin makes the following announcement: "(1) Physicians may obtain antitoxin free from the Antitoxin Stations of the Department for the gratuitous treatment of their charity cases. (2) Physicians may have their prescriptions for antitoxin, to be used in their pay practice, filled by any Antitoxin Station at the following prices: No. 1 (1,000 units), 75 cents; No. 2 (2,000), $1.25; No. 3 (3,000 units), $2.25. The physician obtaining free antitoxin receipts for it, and the receipt contains the following certificate: 'I hereby certify that the family of this patient is unable to pay for the antitoxin; that the case is urgent; that I am attending without fee, and that I will report the termination of the case on the postal card form of the Health Department furnished by the druggist.'"

OBITUARY.

Dr. Charles T. Whybrew died from Bright's disease last Tuesday at his home. He was born in New York sixty-two years ago. He was a graduate of the College of Physicians and Surgeons and was a member of the New York County Medical Society.

Dr. Stanley G. Clarke died last Saturday from heart failure. He was born in Camden, Ont., in 1842, and was a graduate of the University of New York. He began the practice of medicine in Brooklyn about fifteen years ago. He was one of the organizers of the Central Throat Hospital, and had been president of its board of managers. He was a member of the Medical Society of the County of Kings, the Brooklyn Medical Society, and Ridgewood Lodge, No. 710, F. and A. M. He had been an inspector of the Board of Health in Brooklyn for several years.

Dr. Verranus Morse, of Brooklyn, died last Wednesday night from the shock following a fracture of the hip. He was born in Springfield, N. H., in 1818, and was graduated from Dartmouth College in 1845, and from the medical department of the New York University four years later, when he took up the practice of medicine in this city. For many years he was treasurer of the New York Medical Society.

Dr. William J. McDermott, of New York, seventy-three years old, a noted surgeon in the Civil War and a personal friend of Presidents Lincoln and Grant, died Saturday, March 12, at his home after a lingering illness. Dr. McDermott was born in Portland, Me., and received his early education in St. John, N. B. In 1853 he was graduated in medicine, and after two years of study in Europe he began practice in the village of Westchester. Dr. McDermott was elected to the Assembly in 1860. When the first call for troops was issued Dr. McDermott resigned from the Assembly and enlisted as surgeon and went to the front with the Sixth New York Volunteers. At the end of three months the regiment re-enlisted as the Sixty-sixth New York Volunteers under Col. Joseph Pinkney. Dr. McDermott saw much active service. He was with Col. Ellsworth when that officer was shot at Alexandria, and ran to his assistance. He assisted in the amputation of Gen. Howard's arm at the battle of Fair Oaks, and participated in the battle of the Wilderness, being left in charge of the wounded. He was captured and sent to Libby Prison, where, after a short term, he was paroled. Shortly before the close of the war he served under Surgeon-General Baxter, and was mustered out in October, 1865. Returning to Westchester he renewed his practice.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, February 27.

THE KING AND MEDICAL EDUCATION—DEATH OF SIR EDWARD SIEVEKING—HOW A FAMOUS ARTIST HAS ACHIEVED LENGTH OF DAYS—THE DISCOVERER OF THE LARYNGOSCOPE—THE REAL SECRET OF LONGEVITY—THE STATE REGISTRATION OF NURSES.

The King has shown his practical interest in the improvement of medical education by offering to contribute $500 toward the establishment of the proposed Institute of Medical Sciences, of which mention was made in a previous letter. The object of this institute is to concentrate the teaching of the fundamental and ancillary sciences which form the basis of medical training. An appeal to the public was issued not long ago, and at a meeting of the Faculty of Medicine held on February 19, it was announced that the Committee had received promises of donations to the amount of $40,000, including donations from the Presidents of the Royal College of Physicians and the Royal College of Surgeons. Mr. Alfred Beit, the South African millionaire, and Messrs. Rothschild have contributed $25,000 and $2,500, respectively. But on the whole the response so far has not been very encouraging to the promoters of the scheme. A Rockefeller is badly needed to aid the cause of medical education in London.

Sir Edward Sieveking, a physician of some celebrity in his day, has just passed away at the age of 88. He came of German stock and was born in London in 1816. He took his doctor's degree at the University of Edinburgh in 1841, and returning to London was appointed to the staff of St. Mary's Hospital, then newly founded, and later to that of the National Hospital for the Paralyzed and Epileptic. He was physician-in-ordinary to Queen Victoria and to Edward VII., when Prince of Wales, and was appointed Physician Extraordinary to the King in 1901. The great disappointment of Sieveking's life was that he happened to be out of the way when he was wanted to take a share in the treatment of our gracious Sovereign in the attack of typhoid fever which so nearly slit the thread of his life in 1871. As Sieveking could not be found, Gull was called in and took the opportunity of establishing himself as a member of the sick prince's household. Gull had a highly cultivated faculty of ingratiating himself with patients, and he naturally put forth all his powers of captivation at the bedside of the heir to the throne, with the result

that he supplanted Sieveking. *Les absents ont toujours tort,* and royalty never forgave the unlucky physician who did not happen to be at hand when he was wanted. Sieveking was for some years editor of a highly respectable but long defunct periodical called the *Medico-Chirurgical Review* and he contributed largely to the literature of medicine, particularly in the field of nervous diseases, to which his connection with the National Hospital led him to give special attention. Among his works may be mentioned the Croonian Lectures on Localization in Disease, delivered before the London College of Physicians in 1866; a monograph on Epilepsy, a second edition of which appeared in 1861; a "Manual of Pathological Anatomy," produced in conjunction with H. Jones, in 1854, and a book entitled "The Medical Adviser in Life Insurance," which has gone through more than one edition, and which is still of value to physicians who have to make medical examinations on behalf of insurance companies. He was also the inventor of that useful little instrument the esthesiometer. Sieveking was made a knight in 1886 and received the honorary degree of Doctor of Laws from the University of Edinburgh. He was for some time a Vice-President of the Royal College of Physicians. He was a worthy man of whom Tacitus might have said *Bonum virum facile dixeris, magnum libenter.*

On February 23, G. F. Watts, the Royal Academician, one of the most famous of British artists, celebrated his eighty-seventh birthday. Although he is so far declined into the vale of years he still walks as one that remembers that the Creator *Os homini sublime dedit celumque tueri jussit.* He walks without a stick and until a few years ago was known as a bold and skillful rider. He does not need to use spectacles. He rises with the sun and goes to bed with it—at least in summer time, when he is often up and at work on his pictures or statues as early as half-past three. Asked what is the secret of his retention of his powers so far beyond the age when most men are content to vegetate, Mr. Watts said to a sympathetic inquirer: "I have always been very sickly. From my earliest years I have never been robust, and, indeed, for this reason I was compelled to refrain from most of the violent exercises of youth. I neither drank nor smoked, nor did anything, in fact. I am a very negative sort of a person. I have just lived—with the exception, of course, of my work. But although I have been successful, far beyond anything I ever hoped when I began life, I cannot say that the joy of life has ever been mine. I enjoy my work; I am intensely interested in it, and am continually endeavoring to improve, for, if I don't improve now, when shall I ever have a chance of doing so? What I mean is that the buoyant exuberance of animal spirits, which leads many people to rejoice in life for the mere sake of living, I have never known. Nor have I ever shrunk from death. In my works I have endeavored to destroy the fear of death, to cause him to be regarded, not as a dread enemy, but as a kindly friend, and such has ever been my feeling. I should, of course, regret to leave work undone and to part from those friends whom I love; but a sense of the weariness of the world and the suffering and sadness which seem to be inherent in mortal things have weakened if not destroyed that joy of life which is common to most young things. The condition of things in this world, so far as I can see it, full of suffering and sorrow, saddens me. I feel it might have been so much better arranged in many things; and the burden of it weighs upon me. That is one reason why I feel that every theological student, before he applies himself to theology, should be thoroughly grounded in physiology. Too often theologians seem to regard the body with contempt, not to say dislike. To live a healthy life, to have the body in which your soul dwells in good working order—these are surely the first duties of the religious man. How many generations have lived and died in the belief that piety consists in the maceration of the body, and in spending many hours upon their knees crying to God to do this, that and the other for them. Instead, how much better it would have been if they had looked after their own health and looked after their neighbors.' In the long run the body avenges itself upon the soul which neglects or abuses its habitation. Being naturally sickly, I had orders to take care of my body. I have never smoked. Greater things were done in the world, immeasurably greater, before tobacco was discovered, than have ever been done since. The cigarette is the handmaid of idleness. I do not say that possibly it may not be a sedative to overwrought nerves; but overwrought nerves in themselves are things that ought not to be. Of wine I have taken very little. In my earlier years I used to take a little, but for a long time I have never touched any form of alcohol. At meals I never drink anything, not even water. Tea—yes, in moderation. And so with regard to food I have been compelled to be very abstemious—to eat moderately and of simple food, to go to bed early (nine o'clock, for the most part), to rise with the sun, to avoid violent exercise, and to enjoy plenty of fresh air." Certainly Mr. Watts' regimen seems to have developed in him a very remarkable fund of vitality, for a person "naturally sickly."

A still more venerable figure is that of Manuel Garcia, the discoverer of the laryngoscope, who will complete his ninety-ninth year on March 17. He was born at Madrid in 1805, and was the brother of Malibran and the teacher of Jenny Lind and many other famous singers. Till a few years ago he was actively engaged in voice training. He discovered the means of observing the interior of the larynx in 1854, and in the following year read his memorable paper, entitled "Physiological Observations on the Human Voice," before the Royal Society of London. His observations were made on himself, and in his examination he used two mirrors —a small one fixed on a long stem for introduction into the pharynx and a large one which served at once to throw the light—it was that of the British sun!—on the small mirror and to enable the observer to see the image formed thereon. The discovery was treated with indifference, and for years the laryngoscope was spoken of by superior persons in this country as a physiological toy. Garcia's paper fell into the hands of Turck, of Vienna, who, after a short trial, declared that "he was far from entertaining too sanguine hopes about the employment of the laryngeal mirror in practice." Fortunately, the mirrors which Turck threw aside were borrowed by Czermak, the physiologist of Budapest, who quickly saw to what good use they might be put. He substituted artificial illumination for the uncertain light of the sun. The light was reflected and concentrated by a large ophthalmoscopic mirror. He had mirrors of different sizes and finally the art of laryngoscopy was presented in a practicable shape to the medical world in a paper which appeared in the *Wiener medizinische Wochenschrift* of March 27, 1858. Among the honors conferred on Manuel Garcia in recognition of his discovery is the degree of Doctor of Medicine, which was given him *honoris causâ* by the University of Königsberg.

The mention of these "grand old men," Watts and Garcia, recalls a recent utterance of a London Coroner, Dr. Wynn Westcott, on the secret of longevity. At an inquest held on the body of an old woman who died

in the Hackney Infirmary at the age of ninety-six, the Coroner remarked that, as usual when an inquest was held on a very old person, it was found that he or she had been an inmate of an infirmary or a workhouse. He attributed this to the regular mode of life to which paupers had of necessity to submit. There can be no doubt that luxury kills more than want, and an English workhouse is an ideal place for the practice of temperance. But the Coroner did not say whether he considered it worth while to enter a workhouse simply to secure a long lease of quasi-vegetable life.

The bill providing for the State Registration of Nurses, referred to in my last letter has been "blocked," that is, marked for opposition by a member who is acting, doubtless at the instigation of the Central Committee of London Hospitals. This body, as has already been said, opposes legislation on the subject almost avowedly on the ground of enlightened self-interest. The result of the opposition is that the bill is virtually hung up for the rest of the session. A rival bill is about to be introduced which will in all probability share the same fate. Meanwhile the Committee appointed by the British Medical Association to consider the question is sitting on what, there is too much reason to fear, will prove to be an addled egg.

THE SPREAD OF TYPHOID FEVER BY CONTACT.

To the Editor of the Medical News:

Sir: In your issue of March 5, in an editorial reference to two communications by Dr. Weil, on typhoid fever in Germany, you make the following statement: "The writer, an American, who had the good fortune to be engaged in the service of the German government as regular 'assistant' in a typhoid laboratory in Elsass, gained exceptional opportunities to study the development of the epidemics which were at that time prevalent. After a careful study of all the factors involved he found himself driven to the conclusion that the water supply played no part in the dissemination of the epidemic, but that the infection was in each case communicated from man to man by personal contact."

"The latter brings home an idea, which is by no means new, inasmuch as it is now more than a year since Koch propounded the theory of 'contact infection,' in typhoid; but *which is still somewhat foreign to Americans.* (Italics mine.) The great German bacteriologist asserted that practically every case of typhoid was due to transference of infected material either mediately or immediately from the person of one victim to the mouth of the next. It appears, however, that the theory is not original even with Koch, but goes back far into the dim and anti-bacteriological days of medicine; since the clinicians of the earlier part of the century, among them Bretonneau and Trousseau, held firmly to it."

Now, Mr. Editor, I must say that your statement that contact infection in typhoid fever is still somewhat foreign to Americans, shows most conclusively that you are not very familiar with recent American literature concerning this disease. In the year 1900 (four years ago) there was published by the Government Printing Office a book of 239 pages, the title of which is as follows: "Abstract of Report on the Origin and Spread of Typhoid Fever in U. S. Military Camps during the Spanish War of 1898." In this report it is shown conclusively that typhoid fever was not disseminated to any large extent by drinking water, but that the chief agent in the dissemination of the disease was contact. Please permit me to give you a few quotations from the conclusions arrived at by the commission that studied typhoid fever in 1898. Some of these are as follows:

"(26) Infected water was not an important factor in the spread of typhoid fever in the national encampments in 1898.

"(29) It is more than likely that men transported infected material on their persons or in their clothing, and thus disseminated the disease.

"(30) Typhoid fever, as it developed in the regimental organizations, was characterized by a series of company epidemics, each one having more or less perfectly its own individual characteristics. The truth of this statement will be evident after the inspection of the charts showing the distribution of typhoid fever among the companies of the different regiments. On making such an examination one must be impressed with the fact so plainly evident there that men who are closely associated developed typhoid fever simultaneously. Men in the same company came down with the disease on the same day. This is still more marked when we study the cases with reference to the tents occupied by the men. Of 1,608 cases of typhoid fever which we have been able to accurately locate in the particular tents in which they occurred, together with the date of commencement of the attack, the results may be summarized as follows: Directly connectable attacks, 563, or 35.01 per cent.; indirectly connectable attacks, 447, or 27.79 per cent. Total connectable attacks, 1,010, or 62.80 per cent. Certain tents were badly infected, and the majority of their inmates developed the disease, while other tents wholly escaped. Blankets and tentage became soiled with typhoid discharges, and in this way the disease was propagated and carried by the company wherever it went. We believe, therefore, that personal contact was a very important factor in the spread of the disease.

"(33) When a command badly infected with typhoid fever changes its location it carries the specific agent of the disease in the bodies of the men, in their clothing, bedding, and tentage.

"(34) Even an ocean voyage does not relieve an infected command of its infection.

"(35) After a command becomes badly infected with typhoid fever, change of location, together with thorough disinfection of all clothing, bedding, etc., is necessary.

"(40) Medical officers should insist that soldiers remove their outer clothing at night when the exigencies of the situation permit. With from 12 to 16 men in a tent, all sleeping in their clothes worn during the day, and possibly with some of them soiled with infected fecal material, the effect upon the general health certainly could not be beneficial, and the possibility of the dissemination of infection must be admitted. If privates in the ranks would give more attention to personal cleanliness and if they were furnished with quarters in which they could keep themselves clean, typhoid fever and other infectious diseases among the troops in the field would be greatly decreased. Our investigations show that tent infection must have been an important factor in the distribution of typhoid fever."

I might give you further quotations, but suffice it to say that no one can look at the chart of typhoid fever in the 15th Minnesota, as given in the volume to which I have referred you and come to any other conclusion than that typhoid fever in that regiment was disseminated largely, if not altogether, by contact. In the complete report, which has not yet been published, ninety-two regiments have been charted, and every chart shows that contact was the principal means by which the disease was spread.

Now, Mr. Editor, I think I am not too positive when I say that whatever Bretonneau or Trousseau may have thought, or whatever Koch propounded "more than a year ago," the fact that typhoid fever is spread largely by contact was first demonstrated by American observers.

W. C. Vaughan.

Ann Arbor, Mich., March 12, 1904.

RELATIVE TO AUTOPSIES IN PUBLIC HOSPITALS.

To the Editor of the MEDICAL NEWS:

SIR: Your editorial in the NEWS of March 5, relative to autopsies in public hospitals, should meet with the approval of the entire medical profession and of the great army of scientists engaged in the study of diseases common to mankind, especially such diseases as Epilepsy and Insanity whose etiology is so obscure at the present time.

To show in part the interest felt in the need of a law permitting autopsies at the Craig Colony, let me quote some extracts from letters I have received on the subject:

Dr. Pearce Bailey—"As President of the New York Neurological Society, I should like to write you to express my conviction of how necessary it is for the good of humanity at large that this Bill be passed. The unfavorable outlook in every case of epilepsy is due, in large part, to the fact that we do not understand what epilepsy is. We can never hope to understand what it is unless we have the fullest opportunity to investigate its underlying causes, and of course the first thing to do is to have larger opportunities for systematic examination of the brains of persons dying of epilepsy."

Dr. Adolph Meyer—"I heartily approve of the reintroduction of the Bill concerning autopsies. The scientific side of the question needs no argument. Autopsies must be available to complete our information about the nature of diseases. In these days when it is possible to perform complete autopsies without any disfigurement or other unpleasant effects on the feelings of friends, we can only make superstition responsible for the objection of people who mistake an opposition of spirit for liberty."

Dr. Frederick Peterson—"It seems to me that such a Bill should be passed. It is certainly in the interest of the epileptic, whose disease needs to be more thoroughly studied than it ever has been before, to the end that we may ultimately discover some means of cure. All of the cases that die at the Colony should be scientifically investigated."

Dr. Roswell Park—"In the interest of science, I think it one of the most important measures of recent years. Any disease of such unknown and mysterious nature as to justify a State institution for the care of sufferers from it, not only justifies, but demands, a most painstaking search into the causes. There never has been in the world such an opportunity afforded for careful study of epilepsy as is now afforded at the Craig Colony, and it would be a great misfortune should morbid sentiment be allowed to interfere with the scientific side of the disease. It seems to me that not only should autopsies be permitted but required, and that every laboratory convenience for its study should be afforded in this research."

Dr. M. Allen Starr—"I am heartily in favor of the Bill. If the Craig Colony is to be of use to the general public as well as to the poor victims of epilepsy, it is only by means of scientific work on the subject."

Dr. Samuel B. Ward—"It appears to me that such permission is very desirable in the interests of science, and will be no hardship to anyone. The Bill certainly ought to pass."

Dr. Henry Hun—"The most important method of study, in my judgment, is the comparison of symptoms observed during life with the lesions found in the nervous system after death. To do this, of course, autopsies are essential. It is most important that autopsies should be promptly held in all cases of death. The Craig Colony should not degenerate into a mere boarding-house for epileptics. The many cases gathered together there should be carefully studied."

Bishop Potter—"Prejudice against such autopsies as you refer to has always struck me as singularly unintelligible. Unless we can look to a public institution to contribute such scientific knowledge as it may be within its reach to obtain, we are punishing the whole community for a somewhat artificial and sentimental forbearance in the case of individuals. That scientific investigations of the bodies of the dead have been of great value in protecting the living, is a fact about which there can be no question. And while I should be disposed to treat the feelings of the surviving relatives with consideration, I think that the bodies of epileptics that die at the Craig Colony should be within the control of the Trustees for such beneficent ends as scientific inquiry may serve."

Dr. Hamilton D. Way—"I trust such Bill may become a law on account of the benefit conferred thereby upon medicine through increased opportunity for dead house study and observation in those cases clinically noted during life."

Dr. E. V. Stoddard—"I think there is no doubt as to the advisability of granting the privilege of making autopsies in certain cases at the Craig Colony. In establishing that institution, the state provided for securing 'the humane, curative, scientific and economical care and treatment of epileptics, exclusive of insane epileptics.'"

Dr. Joseph D. Bryant—"It seems somewhat strange to me that at this day of scientific medical advance and practical escape from the popular prejudice regarding autopsies, than any other idea than one prompting early and free appliance of the only attainable means of affording relief from the physical confusion and mental despair always present with epilepsy, should be manifest. I cannot express it too strongly,—not only the great importance but the great need of early performance of autopsies in this disease,—and I sincerely hope that legal permission will be given for the purpose."

The Craig Colony for Epileptics, Mr. Editor, is deeply interested in the fate of Assembly Bill No. 227. It has happened in the past that we have been denied autopsies in the most valuable cases (such cases having been maintained wholly at the public expense at the Colony for years), the only reason for such refusal being founded on sentiment. This, to be sure, should always be respected, but in these days when autopsies are so carefully made without disfigurement, it would seem that mere sentiment should not be permitted to have the last say in a scientific matter of such vital importance to mankind generally.

The Colony respectfully urges that physicians generally will write members of the legislature of the respective districts, urging the passage of the Craig Colony Autopsy Bill, in the form in which it was introduced as follows:

Assembly Bill No. 227, "An Act to Amend the State Charities Law in Relation to Autopsies at the Craig Colony for Epileptics."

"Section XI. Have power (the superintendent), subject to the supervision and control of the Board of Managers, in case of the death of any patient at such institution, who shall have been maintained therein wholly at the public expense, to make, or cause to be made, an autopsy on the body of such patient."

Very truly yours,

W. P. SPRATLING, M.D.,

Medical Superintendent Craig Colony for Epileptics.

SONYEA, March 10, 1904.

PNEUMONIA AS AN INFECTIOUS DISEASE.—The Rochester Health Bureau has decided to treat pneumonia as an infectious disease, and to ask physicians to report all cases just as they report diphtheria and smallpox.

SOCIETY PROCEEDINGS.

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.*

Fifth Regular Meeting, February 17, 1904.

The President, S. J. Meltzer, M.D., in the Chair.

Members Present.—Adler, Calkins, Crampton, Dunham, Ewing, Gies, Jackson, Levene, Lusk, Meltzer, Murlin, Norris, Richards, Wadsworth, Wallace, Wilson, Woodworth, Yatsu.

ABSTRACTS OF THE REPORTS OF ORIGINAL RESEARCHES.†

The Nature and Basis of Sexual Selection in Moths.—By Dr. H. E. Crampton. The object of the investigation described was to obtain a quantitative expression for the strength of the mating instinct in certain species of large Saturnid moths (*Philosamia cynthia* and *Samia cecropia*), and to determine the correlation between the mating instinct and structural characters. The results of earlier statistical studies upon the pupæ of these species were reviewed, dealing with the nature and basis of the process of natural selection during the period before emergence and at emergence. It was shown that (1) those pupæ which die after pupation and prior to metamorphosis are structurally different from and more variable than those individuals which successfully survive the pupal period, (2) those pupæ which become perfect moths are likewise different from those which cannot emerge as perfect moths, and (3) the basis for selective elimination is to be sought in correlation between the various structures. The mating period follows immediately after metamorphosis, when certain individuals with weak mating instincts fail to take part in the production of the next generation, and are thus "sexually eliminated." In order to determine the points mentioned above, pupæ of the two species named were isolated as the time for metamorphosis approached, and upon emergence were given one opportunity to mate. It was therefore possible to compare the pupæ of the two classes of mating and non-mating individuals. The results, briefly stated, are (1) that even slightly imperfect moths possess very little mating instinct, or in other words, that with the structural conditions associated with an imperfect power of emergence, is correlated a low grade of mating ability; (2) that the mating individuals of the perfect class differ structurally to a certain extent from the non-mating ones, but they are very much less variable than the latter class The importance of these results from the standpoints of inheritance and evolution is sufficiently clear to render extended discussion unnecessary.

Observations on a Serous Fluid of Unusually High Molecular Concentration.—By Dr. E. K. Dunham. The fluid was removed from the pleural cavity of a man suffering from lobar pneumonia. The patient was a scene-shifter in a theater and had suffered considerable pain in the chest for four months before his admission to the hospital. His occupation required severe labor for brief periods, during which he became much heated, with intervals of leisure and exposure to cold drafts of air. The immediate reasons for his admission were a chill and inability to continue work. There was nothing unusual in the clinical course of the pneumonia or peculiar in his treatment. A few days after he entered the hospital 400 c.c. of a clear serous fluid was aspirated from the affected side of the chest and was examined on the same day, with the following results: Distinctly alkaline; specific gravity 1.021; depression of freezing point 1.383° C (mean of three examinations with different portions of the fluid, 1.395, 1.385 and 1.370° C. respectively); electricial conductivity 0.009119; chlorine calculated as sodium chloride 0.58 per cent.; total nitrogen 0.84 per cent.; nitrogen from washed tannic acid precipitate expressed in percentage of the fluid 0.83 per cent.; proteid (N x 6.25), 5.21 per cent. of the fluid; traces of reducing substance (sugar ?) after removing proteids with ferric acetate; traces of nitrogen liberated by hypobromite of soda; no extractives of appreciable amount upon shaking with ether, acetic ether or chloroform.

The matter of chief interest in the results was the considerable depression of the freezing point —0.81° C. greater than that by the blood, which was found to be 0.57° C. This 0.81° C. represents nearly 0.438 gram-molecule in solution in excess of the molecular concentration of the blood, and appears to be a clear indication that osmotic interchanges between this fluid and the blood did not freely take place, possibly because of a thick layer of fibrin upon the pleural surfaces. Such a deposit would not, however, explain the high molecular concentration of the fluid. It appears most probable that this was produced subsequent to the formation of the fluid, by changes in the larger molecules originally present in solution or by the solution of substances not at first dissolved. These substances could not be dissociable, because the electrical conductivity was rather lower than is usual in such fluids. If the substances causing the high molecular concentration were organic compounds, they were not extractives soluble in ether, acetic ether or chloroform.

On the assumption that cleavage products of proteid substances, precipitable with tannic acid, might be present and cause the unusual depression of the freezing point, the following experiments were made: Sterile horse serum, which had not been subjected to heat, was divided into portions. Of these some were kept for controls and others were inoculated with pure cultures of *Staphylococcus pyogenes aureus* or Fraenkel's pneumococcus. Freezing-point determinations were made on certain of these portions and the rest were sealed up in pipettes holding 100 c.c. each. These were incubated at 37° C. for a week, when freezing-point determinations were made on one of the controls and one of the tubes inoculated with each of the bacteria mentioned. Cultures at this time showed the presence of great numbers of the species used, with no admixture of other species. The remaining tubes were left in the incubator for several months, when cultures proved to be sterile. The results of physico-chemical examination of these sera are tabulated below:

HORSE SERUM A

	Sterile Controls ° C		Inoculated with Staphylococcus. ° C	
1903				
May 19,	Δ=0.580°;	K=0.009394	Δ=0.585°;	K=0.009370
May 26,	Δ=0.580°;	K=0.009491	Δ=0.585°;	K=0.009674
1904				
Jan. 16,	Δ=0.590°;	K=0.009684	Δ=0.640°;	K=0.010128

HORSE SERUM B

	Sterile Controls ° C		Inoculated with Pneumococcus. ° C	
1903				
May 21,	Δ=0.560°;	K=0.009516	———	———
May 28,	Δ=0.560°;	K=0.009516	Δ=0.580°	———
1904				
Jan. 15,	Δ=0.600°;	K=0.009897	Δ=0.640°;	K=0.010372

These data show but slight changes in the molecular concentration of the sera, and such changes as have occurred occasion an increase in the electrical conduc-

* Proceedings reported by the Secretary, William J. Gies, New York.

† The authors of the reports have furnished the abstracts. The Secretary has made only a few abbreviations and minor alterations in them.

tivity as well as in the depression of the freezing point, showing that dissociable bodies have been produced. The experiments, therefore, fail to explain the high molecular concentration of the serous fluid from the chest, but it is possible that further experimentation in this direction will be more successful.

An Experimental Study of the Eosinophile Cells During Infection with an Animal Parasite—Trichina Spiralis.—By Dr. Eugene L. Opie. (Presented by Dr. James Ewing.) The administration of *Trichina spiralis* to the guinea-pig causes an increase of the eosinophile leucocytes in the blood comparable to that which accompanies human infection. There is no constant alteration of the number of these cells until the end of the second week after infection, when their relative and absolute number rapidly increases and reaches a maximum at the end of the third week. At this time embryonic trichinæ are in process of transmission from the intestinal mucosa by way of the lymphatic vessels and the blood through the lungs to the vascular system. Eosinophile cells accumulate in the mesenteric lymph glands and in the lungs and form foci which resemble small abscesses in which polynuclear leucocytes are replaced by eosinophile cells. These cells are provided with polymorphous nuclei and do not differ from the eosinophile leucocytes of the circulating blood. Accumulation of the eosinophile cells in the mesenteric lymph glands and in the lungs is explained by the transmission of the embryonic parasites through these organs. Increase of eosinophile cells in the blood and in other organs is accompanied by characteristic changes in the bone marrow. The fat is diminished in amount and cellular elements replace it. Cells with eosinophile granulation are present in immense number and particularly numerous are the eosinophile myelocytes, cells peculiar to the bone marrow. Eosinophile cells undergoing mitatic division are more numerous than usual. The number of eosinophile leucocytes in the blood always diminishes before death so that the proportion is usually less than one per cent. Infection with a very large number of trichinæ causes a rapid diminution of the number of eosinophile leucocytes and is quickly fatal. The eosinophile cells of the bone marrow exhibit degenerative changes of which nuclear fragmentation is most characteristic. Similar changes may affect the eosinophile cells of the intestinal mucosa and of the mesenteric glands. Mild infection stimulates the eosinophile cells to multiply, but severe infection causes destruction.

Subcortical Expressive Reflexes and their Spinal Pathways.—Dr. R. S. Woodworth reported interestingly on some experiments done in collaboration with Professor Sherrington in the latter's laboratory. It was shown that in a recently decerebrated cat, powerful sensory stimuli evoked reactions such as in a normal animal would be expressive of pain, anger, and other similar emotions. Such reactions are therefore primarily subcortical reflexes, and not dependent on the organ of consciousness. The "ether cry" also appeared in decerebrate animals. The sensory spinal pathway, by which these signs of pain were aroused, was found by experiments in which partial cross sections of the cord were made, to run not in the posterior but in the lateral columns. The pain pathway from either side of the body runs up both halves of the cord, but more largely up the opposite half.

An Experimental Study of the Cause of Shock.—W. H. Howell. (Presented by S. J. Meltzer.) Prof. Howell's experiments were made upon dogs anesthetized with morphine and ether and brought into a condition of shock by operations of various kinds. Blood-pressure records were obtained in the usual way during the experiment. The following general conclusions were reached: (1) The most important and dangerous feature of severe shock is a long-continued, practically permanent fall in blood pressure to about 20 to 40 mms. of Hg. This condition is designated as vascular shock and is due to a long-lasting loss of activity of the vasoconstrictor centre. (2) A second important result of shock is a very rapid and feeble heart-beat. This condition is designated as cardiac shock; since, although it may result secondarily from the permanent fall in blood-pressure it may also occur quite independently of the vascular shock as a primary result of the operations. Cardiac shock, as far at least as the rate of beat is concerned, is due to a more or less permanent loss of activity of the cardio-inhibitory center. (3) Intravenous infusions of alkaline salt solutions (NaCl 0.6 per cent., Na_2CO_3 0.5 per cent.) cause a rise of pressure by increasing the force of the heart-beat. The effect is more durable than with salt solution alone and may be renewed by repeating the injection. (4) The fundamental cause of vascular and cardiac shock is not exhaustion of the vasomotor and cardio-inhibitory centres from over-activity, but a more or less permanent inhibition of these centres from excessive stimulation of the inhibitory paths.

New Members.—Drs. Isaac Levin and J. P. Atkinson were elected to membership.

Officers for the ensuing term were elected as follows: President, S. J. Meltzer. Vice-President, James Ewing; Secretary, William J. Gies; Librarian, Graham Lusk; Treasurer, Gary N. Calkins.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedic Surgery.

Stated Meeting, held February 19, 1904.

The President, Homer Gibney, M.D., in the Chair.

Arthropathies of Locomotor Ataxia.—Dr. George R. Elliott presented several patients from the Montefiore Home. He said that in the first patient the left knee was the only joint affected, showing genu inversum, which should not be confounded with primary genu valgum. There was a certain enlargement of the head of the tibia, edema about the knee-joint and enlargement of the leg and thigh. The left leg and thigh measured one inch more than the right. Incidentally, he wishes to refer to the patient's chief subjective symptom—a metatarsal pain. Four operations have failed to relieve this troublesome symptom. The second patient shown was a man of about fifty-seven years, confined to a wheel-chair and bed. The joints involved were the small joints of the fingers, chiefly the first phalangeal joints. These deformities were globular in shape, painless and devoid of swelling and have been so from the beginning. The patient in his wheel-chair with overcoat on, placed the heels of both feet behind his head, demonstrating the condition common in locomotor ataxia known as muscular hypotonia. The doctor further presented a cast of the hand of a third patient who was unable to be moved. The cast showed very marked globular swellings of the phalangeal joints. This patient also had a very marked arthropathy of the left shoulder so badly involved that he could dislocate the joint at will. The head of the bone was markedly enlarged, the acetabulum filled up and destruction of the capsule and ligaments—all painless from the beginning. Neuropathic arthropathies are not confined to locomotor ataxia, but are found in syringomyelia and certain other special cord diseases. As in the present cases, the characteristic manifestations are rather sudden onset of a painless swelling, usually globular in shape, with partial subsidence and recur-

rence. The globular shape and absence of redness and pain differentiate it from the spindle-shaped, painful swelling of arthritis deformans. Section of an advanced arthropathic joint shows destructive changes. There are usually laxity of the ligaments, rarefaction of the bony parts, general edema about the joint, which extends into and along the limb. It is not an edema that pits on pressure. Only 3 to 4 per cent. of all tabetic patients manifest arthropathies. Statistics show that the affected joints are much more frequent in the lower extremities and not at all common in the small joints, seen in the two cases presented.

Dr. V. P. Gibney, in the discussion, said he thought the laxity of muscles in Case II very interesting, and wanted to know whether that was a common feature of the disease. He thought it extraordinary to see a patient as old as this man, with ligaments so relaxed as to enable him to put his legs over the back of his neck. In those cases he had seen, the laxity of ligaments was in the ankles and knees. The other case was interesting on account of the neuralgia in the internal plantar, and failure to get relief after section of the nerve, but he presumed that the tabes from which the man suffered, rather ruled it out as a case of metatarsalgia.

Dr. R. Sayre said he was sorry not to have heard the remarks on the cases when presented. He had not seen the man's hip, nor seen him standing, but he thought possibly he might be fitted with hip-splint apparatus to hold the hip so he could walk, if simply the ligaments were at fault, through relaxation. In many cases the relaxation affects the joints of knees and ankles as well. Dr. Sayre had had many cases where the patients could walk around comfortably with lateral support on knees, where they were incapable of standing without this support, the ligaments being so relaxed. In these cases the joints are very prone to luxate.

Dr. Brewer said he was interested in the case reported. He had treated a similar case: A neurotic boy who complained of pain in the metatarsal joint of the great toe. He could not step nor walk. There was an extremely tender point over the joint, which was a little thickened and reddened. He had worn a badly fitting shoe, which perhaps caused slight deviation of the toe. The joint was opened and found to be healthy. A little piece of bone was taken away, and the pain was relieved. A return of acute pain occurred, which was relieved by the application of the cautery. This relief continued for a number of weeks, but the pain returned so severely the boy could do nothing. He was in a hysterical, nervous state. He was seen by Dr. Blake in Dr. Brewer's absence, who took out one inch of the internal plantar nerve, affording relief. Three months later, he again operated and took out the whole of the nerve, which presented a small neurofibroma near its origin. The pain came back after a while and the boy underwent a fourth operation, this time Dr. Bull operating. In about three months there was a fifth operation, the result of which is unknown. Dr. Brewer would like more light on the subject of these cases. He thought it rather common to find such laxity of the hip ligaments from non-use, that the case was not extraordinary.

Dr. Elliott said he believed it was a common symptom of locomotor ataxia, known as hypertonia, and, he believed, an early symptom. Neurologists present would doubtless settle that question. In reply to Dr. Gibney he said he believed the condition common. (Reference made by Dr. Gibney to the man putting his foot over his head.) It had nothing to do with arthropathy. In the patient he had presented, there were no changes in the hip-joints. It was due entirely to loss of muscular tone.

Dr. Dana said he could only confirm Dr. Elliott's statement that there is this relaxation, very marked, in most cases of arthropathies, usually associated with atrophy of the head of the bone. He was interested in hearing the remarks about splints for the joints. He thought it a mistake always to put splints on tabetic joints. He cited a case in illustration.

Dr. Brewer said that he believed the case he cited was one of psychosis, and that there was no organic disease of the nerve.

Dr. Sayre said that in marked relaxation of ligaments it was sometimes quite possible to slip the femur on the tibia; when the patient is upright and moves in any direction, there is danger of complete luxation of the joint, and possible rupture of the skin as well by constant violent slips. He had seen those who were incapacitated from going about except on two crutches, who, when properly fitted with apparatus, could walk without a cane. There was sufficient muscular power and sufficient coordination of the muscles to move the legs in anteroposterior motion, if something was put on to limit the lateral deviation. The speaker had a case of Charcot's disease of the ankle in which the ankle resembled osteosarcoma; there was the egg-shell crackling seen in malignant bone diseases. The patient was locked up in a plaster-of-Paris boot from the toe to the knee, in which he walked for a number of months, when a large part of the disability disappeared. In this case, back of the tabes, he had a syphilitic history. He was put on antisyphilitic medicine in large doses. The foot responded beautifully, and the incoordination disappeared. The man still retains his pin point pupils.

Lumbar Pott's Disease.—Dr. Homer Gibney presented a child of twenty months from the Dispensary of New York Hospital, referred as case of lumbar Pott's disease. No disease of the spine was, however, found, but a very marked scorbutic condition in addition to a pronounced general rachitis. The scorbutus responded quickly to treatment and the long posterior rachitic spinal curvature is yielding to a perfectly fitted frame on which the child is placed and mother instructed as to its management.

Acute Infectious Osteomyelitis of the Spine and the Acute Suppurative Perimeningitis.—This was the paper of the evening and was read by Dr. J. Ramsay Hunt.

Dr. Brewer, in the discussion, said he had only seen two such cases, both unrecognized at the time he first saw them. He had been looking for a comprehensive paper giving fuller statistics than could be found in abstracts from foreign literature, and such a paper had been read this evening. He thought it most valuable from a surgical point of view. In each of Dr. Brewer's cases there was a perirenal abscess. The pus was found to issue from diseased vertebral bodies. In both cases there was extreme sepsis. He supposed at first that the trouble came from the kidney. After exploring the kidney and finding it normal, he made a small opening in the psoas, then into the vertebral column, and removed the sequestrum. The first patient died in a week or ten days. After death an autopsy revealed a very extensive process. In the second case, a man had chills and fever, and complained of pain in the back, which had been relieved for a number of days before Dr. Brewer saw him; and with the relief of pain, there was the formation of a large lumbar indurated mass. This was opened. At the first operation a quart of pus was evacuated. The septic symptoms abated, but there was no closure of the sinus. A second operation

was done to remove a supposed diseased and suppurating kidney. By making a large incision, the region of the kidney was exposed, and found to be normal. The psoas was filled with pus;—also a focus in the body of the vertebra. Dr. Brewer said he had another case, but was not sure it was primary septic osteomyelitis. It occurred in the arch. It was an old case operated on before Dr. Brewer saw it. He simply provided better drainage. He thought these cases should be diagnosticated early, and that one should be on the look-out for them. The rate of mortality was high. The vertebral bodies are inaccessible, and require prompt treatment.

Dr. V. Gibney said that those of the Section who had been handling vertebræ for a great many years would feel especially in sympathy with a differential diagnosis. More cases should be recognized than have been in the past. In regard to prognosis of osteomyelitis of the vertebræ and of the hip, when Mr. Smith, of London, began to report cases, and Mr. McNamara followed, there was frightful mortality. As they were recognized earlier, the mortality was much lessened, because their acute infectious nature was understood and prompt measures were taken to secure relief. In place of dangled hips with a few half-opened abscesses, much better hips are now seen; the surgeon goes at once to the focus of disease, removing sometimes a head lying loose in the cavity, fixes the limb in good position, drains well and gets prompt relief and pretty stable hips. During the last year or two, when so much has been said and observed about congenital hips, he had found cases said to be such hips, with one or two tell-tale sinuses on the outer side of the thigh with history of acute abscess, which had opened when the child began to walk lame. A patient came to see Dr. Gibney recently from a distance, troubled with congenital dislocation. He saw a cicatrix on the inner side of the thigh. He was told that at nine months the child had had an acute attack of hip trouble, the abscess opening and soon healing. When the child began to walk no attention was paid to the hip. There was an inch and a half shortening, and the child was labeled with congenital dislocation of the hip. He thought the points emphasized in Dr. Hunt's paper—early recognition and prompt surgical measures adopted for relief—were very opportune. In regard to pachymeningitis, etc., he was reminded of a neurological experience: Dr. Putzell read a paper when we were finding a number of those cases, and the speaker had put on record two or three cases of peripachymeningitis hypertrophica cervicalis—not acute. Those cases are simply eliminated. We have to recognize the disease as osteomyelitis. We have stopped talking about acute suppurative periosteitis and acute peripheral osteitis. Eight or ten years ago Mr. McNamara showed the speaker specimens in Westminster Hospital, declaring it was general osteomyelitis, and could not fairly be called periostitis.

NORTH BRANCH PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, February 10, 1904.

The Chairman, Dr. Samuel Wolfe, in the Chair.

The Unique Position and Value of Mercury in Therapeutics.—Dr. I. Newton Snively read this paper. He stated that in the frequency of its employment, it compared favorably with iron, but that here the similarity ended, the one being a builder up of tissue, while the other is a breaker down of tissue. He called attention to the fact that mercury had through all the ages occupied a prominent position in the materia medica, and reviewed the history of its use and the improvements in its administration in recent years. Without deciding upon the relative cholagogic values of blue mass, calomel and corrosive sublimate, or their means of action, he stated that there was agreement among the profession upon the main indications for the administration of calomel, when such symptoms are present as dull headache, yellow conjunctivia, constipation, sense of weight over the liver; no appetite, and general lassitude, and whether the process takes in one part or the other of the intestinal tract it is agreed that it acts upon the small intestines and upper part of the colon, hastening the contents downward, relieving hepatic engorgement, stimulating intestinal secretions and bile and producing large, watery stools. It is also of value in fractional doses in the early stages of typhoid fever and the diarrheal maladies of childhood. It passes through the stomach unchanged and thus does not interfere with the functions of this organ. Thorough trituration is of value and the joint administration of an alkali, preferably, sodium bicarbonate increases its effectiveness.

Therapeutics of Arsenic.—This paper was read by Dr. Howard S. Anders, in which he stated that the drug was an alterative, and while referring to the fact that the exact conditions produced by it were not known he called attention to the necessity of carefully watching for symptoms of arsenical poisoning when the treatment is long continued. The drug is an improver of nutrition and it would seem to be a direct stimulant to nutrition, by diminishing or checking the tissue change and indirectly it improves the nutrition by increasing the recuperative powers, and it would seem that some individuals need arsenic to create a normal neuromuscular vigor, just as the syphilitic needs the iodides and the chlorotic iron. He referred to the fact that Gautier, of Paris, had discovered arsenic in the human body and also that M. Berhand, of Paris, had discovered it in hens' eggs, which would indicate the necessity for supplying it when absent. In regard to its employment in tuberculosis, he acknoweldged a hesitancy in its use on account of the likelihood of deranging the mucosa. The natural arsenical waters of Levico are valuable in some cases of this disease. He stated that his experience with the drug in the treatment of chorea extended to about twenty cases, in all but two of which the administration in the form of Fowler's solution in gradually ascending doses, in conjunction with dietetic, hygienic and psychic measures was satisfactory. He remarked that in St. Vitus' Dance, the drug seemed to be almost a specific, and believed it was best administered by beginning with about three drops, and increasing about two or three drops each successive day. He referred to the work of Rope, Woxham and others, the latter of whom recommends the hypodermatic use of the arsenite of soda, beginning with one-tenth grain doses and rapidly increasing to one-half or two-thirds grain doses. He considered the drug of great importance in the treatment of chronic malaria, anemias, cachexias, in the recurrent estivo-autumnal malarial fevers, and in intermittent malarial neuralgias. He reported a case of recurrent type, each spring and fall, in which he had secured particularly good results. He also stated that personally he had suffered from tertian malarial fever each spring and autumn until he took the drug off and on for three months, continuing until the first symptoms of gastro-intestinal irritability manifested themselves, since which time (fourteen years ago) he has not had any symptoms of the disease. In certain cases of pernicious anemia and arthritis deformans, he believed that it had a beneficial effect. In scrofulous conditions, glandular enlargement and bronchial catarrhs, it is always of value.

Digitalis.—A paper on this drug was read by Dr. William Egbert Robertson, in which he reviewed the various pharmaceutical preparations and their actions and believed the preparation made from Allen's leaves to be the most valuable. In regard to digitoxin the chemistry is very incomplete; it seems to have some effect in relieving the blood pressure, but during its administration the volume of urine and pulse rate should be noted from time to time in order to avoid the possibility of cumulative action. He referred to the case of a young man, twenty-five years of age, who had suffered from a parenchymatous Bright's disease. He was edematous and constipated, but there were no symptoms of uremia. He was given the infusion for several days, without any apparent effect. One day he got up, walked to the clinic, and before his case could be attended to, he vomited rapidly and showed manifestations of the toxic effect of the cumulative poisoning. Dr. Roberston preferred the infusion, and stated that he had not secured nearly so good results by using the digitalin as by using the digitalis in two-dram doses every three hours. The drug is employed for its effect upon the circulation and especially after loss of cardiac power; in cases of weakness without valvular disease, in simple dilatation; and all forms of valvular heart disease, especially mitral disease, it is of value. In simple hypertrophy, aneurism and a high degree of arterial sclerosis, it is contraindicated.

The discussion was opened by Dr. Hobart A. Hare, who referred to the value of $^1/_{200}$ grain doses of biniodide of mercury, in a watery solution every six to eight hours for the purpose of aborting acute tonsillitis. He believed that all preparations of mercury were contraindicated in cases of tuberculosis and that one of the chief reasons for the value of calomel in cases of intestinal disturbance was on account of its power of eliminating intestinal impurities. He believed arsenic to be of value in tuberculosis and anemia, as are also small doses of arsenate of copper in some cases of the latter disease, when iron does not seem to do so well. In regard to digitalis, he believed chemically and physiologically tested and carefully prepared fluid extract was the best, and recommended that the physician have it put up regularly, of a known strength, at certain reliable pharmacists. He felt that many cases of untoward results in the administration of digitalis were due to the fact that the physician was not thoroughly familiar with the strength. He also referred to the danger of the cumulative effect of digitalis, caused by the non-absorption of the drug at the time of its administration, believing that when the required dose is ascertained, the patient should be kept there, instead of increasing it. Absorption is also aided by the conjoint administration of mild doses of Hoffman's anodyne.

Dr. Ludwig Loeb referred to the value of calomel in conjunction with some active diuretic in the treatment of dropsical conditions. In the administration of mercury in tertiary syphilis and other diseases, it is very apt to produce mercurialism, which should be carefully watched for and the drug discontinued, so soon as these symptoms appear. Arsenic, he remarked, was particularly effective in diseases of the glandular structures. It is also of value in skin diseases, such as psoriasis and lupus, and in anemia. Digitalis, he did not view as a true diuretic, but rather as a heart tonic, acting by stimulation and thus increasing the circulation and secretion of urine.

Dr. Walter I. Pennock referred to the difference in strength of the various drugs put up by the different houses, and urged the necessity for uniformity in this direction. In regard to calomel he believed as good results were secured by fractional doses as the administration of a single large dose. He stated that he had never seen a case of the cumulative action of digitalis, and believed the best results would be produced by use of the fluid extract, and after getting up to a sufficient dose by dropping back again to about half that amount, and again gradually increasing.

Dr. William L. Pepper stated that he had treated 13 cases of diphtheria with biniodide of mercury in one house, all of which recovered.

Dr. I. Newton Snively, in closing, stated that he believed the value of any drug depended upon the amount which was absorbed. In the administration of calomel, he recommended one-tenth of a grain every hour, combined with bicarbonate of soda and thoroughly triturated, and believed that the best results were secured with fractional doses of this drug.

Dr. Howard S. Anders, in closing, believed arsenic to be of value in cases of tuberculosis when fever was absent, and urged the necessity of carefully prepared preparation of digitalis of uniform strength.

Dr. William Egbert Robertson, in closing, stated that he considered the effect of the fluid extract of digitalis upon the stomach less irritating than that of the other preparations. He believed that mercury may produce nephritis, to which Kauffman and other German observers have called attention.

BOOK REVIEWS.

The Medical Epitome Series. Microscopy and Bacteriology. A Manual for Students and Practitioners. By P. E. Archinard, A.M., M.D., Demonstrator of Microscopy and Bacteriology, Tulane University of Louisiana, Medical Department. Series edited by V. C. Pedersen, A.M., M.D., Instructor in Surgery and Assistant Anesthetist at the New York Polyclinic Medical School and Hospital, etc. Illustrated. Lea Bros. & Co., Philadelphia and New York.

This excellent little volume of the Medical Epitome Series affords a concise and clear presentation of the essentials of bacteriology and bacteriological technic without neglecting the more recent achievements of this science such as the Roux-Nocard method of culture. Pathogenic microorganisms other than bacteria, such as streptothrix, plasmodium and ameba are discussed in separate chapters and the final pages are devoted to the bacteriological examination of water, air and soil. Though the book contains but 210 pages it will be found a remarkably complete guide for the laboratory, and a series of questions appended to each chapter will make it handy for the student. Excellent colored illustrations abound throughout the volume.

Hand Atlas of Human Anatomy. By Werner Spalteholz and W. His. Translated by Lewellys F. Barker. 3 Volumes. S. Hirzel, Leipzig. G. E. Stechert, New York.

It has rarely been accorded to the reviewer to have the pleasure of looking over so attractive a work as that under consideration. From the illustrative as well as the scientific side we think this one of the best examples of anatomy making with which we are acquainted.

The work is termed a hand atlas. It is more than this. It almost brings the cadaver to the study table, so realistic are the illustrations and so sharp and vivid the pictures left. With this work the student and the older practitioner as well can rehearse their anatomy without the inconvenience and discomforts of the dissecting room. This feature alone commends it to all who would keep a better grip on their anatomical knowledge, al-

though we hasten to add it can never take the place of the section room for the beginner, notwithstanding its superlative qualities.

But further and behind this excellent illustrative feature, there are more philosophical pedagogic principles involved that render the book, we think, unique. Nowhere, for instance, apart from special monographs, are the intricate anatomical relations of the nervous system set forth as here. The conception of the whole organ with its coordinate relations to other parts of the body is most felicitously set forth.

We can only hope that such a work will meet with a wide recognition that may cheer the economic instincts of publishers and prove the forerunner of a group of text-books on anatomy of similar stamp.

Elementary Bacteriology. By M. L. Dhingra, M.D., C.M.Edin., Diplomate in State Medicine, University of Cambridge, Member of Sanitary Institute, etc. With colored frontispiece and illustrations in the text. Longmans, Green & Co., London, New York and Bombay.

An attempt has been made in this volume to represent in a concise manner the fundamental principles of Bacteriology. The material has been selected and arranged so as to meet the ordinary requirements of Indian students and practitioners, so that typhoid, dysentery, plague, cholera and malaria are treated rather in detail for so small a book. The practical part of the subject is discussed very briefly in a short appendix. The text is interesting and thoroughly up to date.

A Manual of Bacteriology. By Herbert U. Williams, M.D., Professor of Pathology and Bacteriology, Medical Department, University of Buffalo. With ninety-nine illustrations. Third Edition, Revised and Enlarged. P. Blakiston's Son & Co., Philadelphia.

This book is sufficiently long before the profession to demand no more than a passing notice. The plan used in the preceding editions has been followed in the preparation of the present one; the only departures being the insertion of a short, historical sketch and the freer use of references of original articles and reviews. In the author's own words the purpose of the book is to give in the smallest possible space the facts which a physician must know with some of those which it is desirable that he should know and a little of that which he may learn if his needs or inclinations lead him to go further. Much time has been spent on the index, so as to make the contents quickly accessible.

Bacteria, Yeasts, and Molds in the Home. By H. W. Conn, Ph.D., Professor of Biology, Wesleyan University. 293 pages. Illustrated. Ginn & Company, New York.

In preparing this work Prof. Conn has done a real service for all who are interested in household economics, and those who are not thus interested would do well to spend a couple of hours in its perusal. The book is just what it aims to be, a practical and popular epitome of the newer conceptions in bacteriology, in so far as they directly affect the life and well-being of the home. Of especial interest is the chapter on Food Preservatives, which touches on the much discussed question as to the harmfulness of the indiscriminate use of such substances as borax, formalin, salicylic acid, etc. Prof. Conn's conclusions are sound and wholesome, and as such are valuable data on the subject. There are chapters on the care of the sick room, disinfection, infection and immunity, and an appendix describing some simple experiments for those who can fit up inexpensive apparatus. The book is especially valuable to those who are taking up the modern methods of preparing food in our various cooking schools, because it has a truly scientific author who can back up what he says by actual demonstration.

Anatomy Applied to Medicine and Surgery. By D. E. Mundell, B.A., M.D., Professor of Anatomy, Queen's University, Canada. 492 pages. British Whig, Kingston.

We are sorry not to speak more favorably of a work whose author is evidently so well intentioned; for the poor impression which the volume makes on one is probably due to its mechanical rather than to its literary execution. But upon the first page is an inter-leaf with a list of 32 errata which in these days of scientific accuracy among publishers is somewhat disquieting. Then the paper is of an inferior quality and shows blots and blurs of ink in many places which spoil the book's appearance as a keepsake. Upon the whole, however, the volume is rather complete for its size. Each chapter is prefaced by a résumé of the anatomy of the part in question with its relations, landmarks and some account of the diseases to which it is subject, with brief mention of the simpler operations likely to come under the care of the general surgeon. The book just falls short of being indispensable, as it is, there are doubtless many who will find it useful in refreshing their minds when the several exhaustive works in this field are not for the time being available.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Howe's Handbook of Parliamentary Usage. Hinds & Noble, New York.

Précis d'Urologie Clinique. By Drs. A. Letienne et J. Masselin. 8vo, 466 pages. Illustrated. C. Naud, Paris.

A Manual of Medicine. By Dr. W. H. Allchin. Volume 5. 8vo, 687 pages. Illustrated. The Macmillan Co., New York.

The Eye; Its Refraction and Diseases. By Dr. E. E. Gibbons. 8vo, 472 pages. Illustrated. The Macmillan Co., New York.

Laboratory Work in Physiological Chemistry. By H. C. Jackson, Ph.D. Second edition. 8vo, 148 pages. John Wiley & Sons, New York.

Complete Medical Formulary. By Dr. J. C. Wilson. Third revised edition. 264 pages. J. B. Lippincott Co., Philadelphia and New York.

Ophthalmic Science and Practice. By Dr. H. E. Juler. Third edition. 8vo, 733 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

Hand Atlas of Human Anatomy. By Dr. W. Spalteholz. Translated by Dr. L. F. Barker. Three volumes. 8vo, 872 pages. Illustrated. G. E. Stechert, New York.

Diseases of the Nervous System. By Dr. H. Oppenheim. Translated by E. E. Mayer. Second American edition. 8vo, 953 pages. Illustrated. J. B. Lippincott Co., Philadelphia and London.

Text-Book of Legal Medicine and Toxicology. By Drs. Frederick Peterson and Walter S. Haines. Volume 2. 8vo, 825 pages. Illustrated. W. B. Saunders & Co., New York, Philadelphia and London.

PNEUMATIC TOURNIQUETS: WITH ESPECIAL REFERENCE TO THEIR USE IN CRANIOTOMIES.

BY HARVEY CUSHING, M.D.,

OF BALTIMORE;

ASSOCIATE PROFESSOR OF SURGERY, THE JOHNS HOPKINS UNIVERSITY.

SURGEONS and neurologists alike are familiar with the postoperative palsies of the extremities consequent upon the too energetic and prolonged application of an elastic tourniquet. Out of a considerable number of pressure paralyses, which have come under the writer's observation during the past two years, eight of them have thus originated. The greater number of these were of the brachial type, the tourniquet having been employed to render bloodless the field at the elbow usually for resections of the joint. A thin, flabby arm, especially in these cases of joint disease and in spite of all precautions, lends itself readily to such an injury as the poorly protected nerves are easily compressed against the hard shaft of the humerus. The skilful application of the old type of rubber tourniquet, varying it for the individual so that it exerts a compression just sufficient to shut off the arterial supply and yet not enough to harm the nerve trunks, is an art rarely acquired even by an adept hospital orderly, who may have had years of experience.

There remain other objections to its employment. One of these concerns the technic of the operation. The tourniquet usually occupies a position on the borderline of the aseptic field, and when once applied must remain so until the completion of the operation. If once relaxed, and in certain procedures, in amputations or plastic operations on aneurismal sacs for example this may be necessary in order to see whether there is a continuance of any arterial bleeding, it is most difficult to readjust the tourniquet again, should this be desirable, without dislocating all of the clean surroundings, towels, etc., at the wound. A still further drawback from an elastic band, when tightly applied, is the ensuing vasomotor palsy, evidenced by the flushing of the extremity peripheral to the site of application. In a major amputation this produces the "wet stump" oftentimes so annoying to an operator inasmuch as it necessitates drainage which otherwise might have been avoided.

Pain is another objection. In many operative procedures on the extremities, preferably carried out under local anesthesia, the temporary cessation of the local circulation is of great assistance. Patients, however, can endure the discomfort of an elastic tourniquet for a very brief period. It is furthermore a common surgical practice, and one, I think, of questionable merit, to apply an elastic ligature, when necessary to control hemorrhage, in cases of traumatic lacerations of the extremities and to wait until the "shock" from the original traumatism wears away. Such a practice, from afferent impulses of pain due to the tourniquet alone, may add not a little to the already existing vascular depression.

Thus the possibility of paralysis, the difficulties of observing the best technic during the application, removal and especially of reapplication, and the pain when no general anesthetic is administered are all familiar drawbacks to the common form of elastic tourniquet. I think they may be avoided in large measure by the use of tourniquets of another sort.

The suggestion of an inflatable tourniquet doubtless originated in the use of the distensible armlet of the Riva-Rocci blood-pressure apparatus. On one or two occasions I had utilized the apparatus itself as a means of shutting off the circulation during cocaine operations on the hand, by holding the pressure slightly above that of the registered systolic arterial pressure. Objections are self-evident. Although the pressure of the armlet is relatively painless, its slow distention by shutting off the veins before the arteries, causes such an engorgement as to render a clean dissection most difficult. Consequently a similar armlet, though broader, of less distensible rubber and of such quality that it would stand boiling, was constructed, and by connecting it with a bicycle pump of sufficient size one or two quick strokes of the piston sufficed to fill it. Such an arrangement I have made use of many times for cocaine operations on the extremities with the greatest satisfaction. The tourniquet may be adjusted but not blown up until the moment of beginning the operation, and by palpating a peripheral artery one can tell easily when a sufficient degree of inflation has been reached.* When operating on minor cases without an assistant I have used a small bicycle foot-pump, the tourniquet either being adjusted well above the operative field before "cleaning up" or, having been boiled, placed around the member within the aseptic field just before operating. In similar fashion a larger and stronger form of cylinder than those which I have had constructed would answer for use on a muscular thigh or leg.

There is a further and a therapeutic use to which this form of peripheral construction could well be put though I have had little personal experience with this particular variety of tourni-

* It would be a refinement, of course, to insert a manometer in the course of the tube connecting tourniquet and pump, and, after measuring the tension necessary to obliterate the systolic pressure, to carry the pressure in the tourniquet slightly above this point. In a large operating room this could be conveniently and accurately done by having a tank of compressed air by which the tension could be instantly carried to the required number of millimeters of mercury.

quet therapy. Many observations, chiefly by Bier in Griefswald,* have been made to show the healing effect on chronic processes such as joint tuberculosis or the effect in the production of callus and new bone formation in pseudarthroses, etc., which is brought about by the hyperemia that follows a prolonged period of venous congestion ("Biersche Stauung") artificially produced by a loosely wrapped rubber bandage. It would seem that an inflatable tourniquet would in cases of this kind be much more easily applied, less uncomfortable for the patient and much more exact, since it is desirable to accurately regulate the degree of pressure at a certain point between venous and arterial tension.

It is, however, with this form of constriction as an operative rather than as a therapeutic aid that I have had most experience during the past two years; and, above all, in exploratory craniotomies has it been chiefly put to the test.

Since Wagner performed the great service for surgery and neurology of introducing osteoplastic resections of the skull, most operators, who have had frequent occasion to explore the cranial chamber by this method, have learned the value of a tourniquet placed about the fronto-occipital circumference. The bleeding from the long curved incision through the scalp, when this precaution is not taken, is not only the source of annoying delay before it can be sufficiently controlled, but also in the effort to secure the chief vessels there is considerable risk of partially stripping away from the bone the soft parts on which it depends for its subsequent viability. Later, when the bone flap has been elevated, the weight of pendant hemostatic forceps is especially liable to bring this about.

The method commonly employed of encircling the head with a piece of strong rubber tubing in order to control the vessels of the scalp is illustrated by a cut in Kocher's Operationslehre.† An elastic band of this sort may be stripped about the head from occipital base to supraorbital region where it can be knotted or held by a powerful clamp. It requires much practice and skill to properly apply such a tourniquet, and especially in children it is difficult to keep the band in its desired position and to prevent its rolling down over the orbits. In one of my patients, furthermore, it produced a most trying postoperative pressure neuritis of both supraorbitals and one suboccipital nerve after which I permanently abandoned its use.

Owing to the present limitations of our powers of cerebral localization the majority of cases, in which the skull is opened for exploratory purposes for which a wide osteoplastic flap is suitable, possess lesions which are situated well above the level girdled by a cranial tourniquet.‡ As a matter of fact the entire surface of the hemisphere with the exception of the lower part of the frontal and temporal lobe may be exposed.

During the past year and since I have been using a tourniquet of this pattern, eighteen of my series of craniotomies have been in a situation suitable to its use. It may in general terms be said that a large area of resection is as easy (if not easier) to make and heals as rapidly as a small one. The majority of these cases, needless to say, call for an exposure of the pre- or postcentral areas and it is far more simple with a large field of the hemisphere exposed to recognize the central fissure (Rolando) or to pick out with an electrode the motor strip anterior to it than to go through the usual more or less uncertain preliminary measurements and after determining on the scalp the probable situation of an underlying area to attempt its exposure through a small opening. The latter is the common practice. With any tourniquet the chief objection to a large incision, hemorrhage, is removed. The inflatable form, however, has proved so serviceable and personally I have become so dependent upon it that I unhesitatingly recommend it or a similar device to others.

Every surgeon has, of course, his more or less individual method of meeting the difficulties of the usual cranial resections. An osteoplastic opening may be made in the skull cap in various ways, any one of which with sufficient practice may suffice for its end. The trephine, burr, saws of one sort or another, mallet and chisel, the Sudek or the Stelwagon devices, the De Vilbiss or Dahlgren forceps are but a few of them. What may serve one is awkward in the hands of another. All possess advantages and disadvantages. Personally for an osteoplastic resection I use a combined method which has proved so uniformly serviceable that I venture to describe the essential points of the technic. Others doubtless may use quite different methods and ones which are better adapted for their personal needs.

After preparing the patient's head a large square of gauze, wet with bichloride solution, is thrown well over it like a hood. Over this is slipped the tourniquet, which with its connecting tube has been boiled so that it can be handled and adjusted by the operator or assistant. It should fit the head snugly and lie flat against it (Fig. 1). In order to prevent any possible rolling of the tourniquet after inflation, should the shape of the head be poorly adapted to retaining it in place, the edge of the gauze hood may be drawn up over it, fore and aft, and pinned; or else, as I have occasionally done, a longitudinal tape may be used for this same purpose as shown in the accompanying photograph (Fig. 3). The tourniquet is sufficiently narrow (3 cm. on the flat) to lie, as stated above, well below the inferior areas of the motor zone. The tourniquet is then inflated and the shovel-shaped incision of whatever form desired made through gauze hood and scalp to the underlying bone. A momentary bleeding may ensue as the imprisoned vessels of

* August Bier, Hyperämie als Heilmittel. Leipzig, F. C. W. Vogel, 1903, p. 51, "Passive Hyperämie der Glieder durch eine Stauungsbinde."

† Vierte Auflage, 1902, p. 93.

‡ Those who choose to reflect a bone flap in operations on the Gasserian ganglion by the Hartley-Krause method, will, of course, find a tourniquet, inapplicable as it lies across the lower part of the temporal fossa.

the scalp empty themselves. It is only exceptionally necessary to clamp any bleeding points and then only on the concave side of the incision, where some of the veins may have diploetic communications. The convex side, which is the more important, remains dry.

Two openings (in a very large resection three

Fig. 1.

Gauze cap with tourniquet applied before inflation.

may be necessary) are then made through the skull at the angles where the superior or longitudinal portion of the incision joins the vertical sides. A small area of the skull is exposed for this purpose by retracting away the scalp on the concave edge of the incision. The openings are made preferably with a hand trephine of bevel

Fig. 2.

Bone flap elevated after inflation of tourniquet. Dura exposed, showing extradural clot.

pattern which has cutting ridges on the beveled surface. It is well to have the trephine of moderately large size (2 to 3 cm. in diameter) as any unusual amount of hemorrhage from the diploetic sinuses that may be encountered is better controlled through a large opening, or one which may be quickly enlarged if necessary by Rongeur forceps, than through the small perforations usually made. Occasionally in long standing cases of increased intracranial tension, from tumors, etc., the diploetic sinuses may be increased to twice their normal caliber, and owing to the existing stasis their vascular tension may be greatly raised.* A very satisfactory way of controlling bleeding from these diploetic sinuses is to fill the teeth on the bevel of the trephine with bone wax, which, by the rotary motion of the instrument, becomes squeezed into the openings and thus controls the bleeding perfectly. This has been learned from experimental work on dogs, for in these animals peculiar large and symmetrically placed diploetic vessels are normally present.†

Starting from these two trephine openings the lateral edges of the bone flap are then cut in a downward direction with forceps of the De Vil-

Fig. 3.

Showing pump, connecting tube and inflated tourniquet in position; also the longitudinal tape which prevents rolling of the tourniquet after distention in those cases in which the configuration of the head is badly adapted for holding it securely in position.

biss or Dahlgren pattern which answer the purpose well since the skull becomes thinner as one approaches the base of the flap. These linear cuts in the bone should be made parallel to but slightly inside of the lateral edge of the skin incision for reasons to be explained.

A long slightly curved blunt dissector is then passed between the two trephine openings, the dura being carefully separated from the skull as the instrument advances. Alongside this as a guide is passed the end of a Gigli wire saw and the longitudinal or superior side of the bone

* It is needless to say here that for this same reason any possible pressure on the neck from position of the head, towels, etc., which can in any way press even lightly upon the jugular vessels should, in intracranial work, be studiously avoided.

† They have been described in the Mitteilungen aus den Grenzgebieten d. Med. u. Chir., Bd. IX, 1902, p. 780.

quickly sawed through on a distinct bevel, the original guide meanwhile remaining in place to protect the dura by holding it away from the wire saw. The flap is then carefully elevated and broken through at its base (Fig. 2).

This entire procedure I have carried out in young adults in seven minutes. Some skulls, especially those of the negro, may require more than double this time. Speed, however, is no criterion of the desirability of a method. Those who are accustomed to follow the changes of blood pressure during critical operative procedures are well aware that rapidity, provided it is gained by the sacrifice of blood, is the least desirable of qualities.

Nothing need be said here of the means of controlling hemorrhage during the further course of an exploration save that in cases of extirpation it is well even at the expense of time to doubly ligate with delicate silk strands, passed through the brain substance with fine curved needles, all the surface vessels of any size which radiate from the area to be removed. The incision through the cortical substance made between the double ligatures thus placed, may be quite dry and what little bleeding may come from the base of the excavation is usually perfectly controlled by a few moments gentle pressure with dry sterile absorbent cotton. Dry gauze is very destructive to raw cerebral tissue. A special technic is required to prevent bleeding from the communications with the longitudinal sinus in case the exploration must pass across the median line and more particularly if it is desired to expose the leg area of the motor cortex, for it lies almost entirely under the Lacunæ laterales of the sinus into which project the Pacchionian bodies. In man there is no more difficult part of the cortex to expose than this portion of the precentral sulcus. This is, however, "another story."

On replacing the bone flap, the importance of the oblique shelf of bone made by the Gigli saw is apparent for without this the desired amount of pressure subsequently to be put upon the dressings could not be exerted without driving in the resected island of bone. Ordinarily no ligatures whatever are placed in the scalp but the edges of the incision are approximated with painstaking accuracy. For this purpose fine interrupted black silk sutures and intestinal needles are used. In this way by an exact and snug coaptation of the edges and by the slight compression of the dressing over the line of incision thus united, against the solid underlying bone, the divided vessels of the incision may be controlled. It will be remembered that the bony part of the flap is cut concentric with but a somewhat smaller diameter than the scalp incision. The local portion of the dressing over the wound is applied before the tourniquet is allowed to collapse and is removed from the head.

Though rarely, drainage may occasionally be necessary. When so, it is inadvisable to drain directly through the incision. A better practice is to lead the strip of gauze or protective or a silver tube such as Kocher employs through a small opening made 2 or 3 cm. outside of the original incision. It is perhaps well to err on the side of drainage rather than otherwise, though in the majority of instances I find it unnecessary. Once only in a long series of cases have I regretted it for in this case the bone flap became elevated by an underlying clot and the wound had to be reopened.

In cases of exploration for cerebral tumors, provided the growth is not found or proves inaccessible, I unhesitatingly remove the bone portion of the flap extensive though it be, make no effort to close the dura over the bulging brain, and carefully unite the scalp as described above. It is in these palliative operations that the importance of an accurate approximation is most evident since with early and perfect healing a large hernia may develop without separating the skin incision. By taking these precautions I have never yet seen the lamentable sequence of a fungus cerebri develop. In one case only in my series has this occurred, and it might have been avoided had I at the time had a wider experience. The case was one in which I successfully extirpated a solitary tubercle of the cerebellum, but instead of closing the wound or of draining over the edge of bone from the outside of my original incision, I drained directly into the cavity left by the extirpation through the latter. In the course of a few days a hernia developed with a fungus cerebri, which protruded through the opening where the drain had been inserted, and in spite of all precautions infection ultimately led to the death of the patient some three months after the operation.

It is customary to make the first dressing in the ordinary run of cases on the second day after the operation, at which time the fine sutures are all removed from the line of incision. The delicate scar receives its subsequent support by placing over it long strips of gauze saturated in collodion. No further dressings are necessary, and this hard protective covering is then left untouched for two weeks or more. No cases, when handled properly, are technically so simple, nor have such an uneventful convalescence as these very cases of exploratory craniotomy—for unlike similar abdominal explorations a period of recumbency after the operation is not essential.

Not the least factor in simplifying the procedure is the use of the inflatable tourniquet, and the belief that such an apparatus has heretofore not been used is the chief reason for making this communication.

The Etiological Relation Between Trauma and Tabes.—In the strictest sense, according to A. Schittenhelm (Deut. Zeitsch. f. Nervenheilk., Nov. 10, 1903) there is no such condition as traumatic tabes, but rather in all those cases in which tabes follows a traumatism, the latter is to be regarded as an accessory or exciting cause, leading to a predisposition, or in the presence of an actual predisposition to tabes, tending to enkindle it or serving to unmask a latent tabes and to accelerate its progress.

A CASE OF STRANGULATED INGUINAL HERNIA: DEATH FROM FECAL DROWNING DURING ETHERIZATION.

BY EDWARD H. GOODMAN, M.D.,
OF PHILADELPHIA.

Patient was a white male, sixty-five years old and was admitted to the men's surgical ward of the Presbyterian Hospital during the service of Dr. Henry R. Wharton, with the following history:

Patient had been suffering with a large inguinal (scrotal) hernia for a number of years, but had received no treatment for the condition, apart from wearing a truss at rare intervals, and then for a short time only. Lately the hernia had grown larger, but not until two days ago had it given him any inconvenience apart from that caused by the size. Two days ago (June 10, 1903) he began to feel some discomfort in the inguinal region, was nauseated and vomited at intervals. His family were unable to state whether the vomitus was fecal in character, but said it was a "dark-looking fluid." Constipation was not absolute at first but became so rapidly, and his general symptoms became so severe that he was removed to the hospital. While in the ward his vomiting was stercoraceous. The scrotum was distended enormously, being as large as, if not larger than, a football, and the penis was almost invisible, save for a slight wrinkling of the skin indicating the prepuce. He was admitted to the hospital 12:45 P.M., June 12, 1903. The condition was diagnosed as strangulated inguinal hernia, and the patient was prepared for immediate operation. On admission his temperature was 97° F., pulse 108, and respirations 24.

Before ether was administered, examination of the patient showed him to be in poor condition; his pulse was 100 per minute, not strong and rather irregular and his respirations were 36. Face was somewhat cyanosed, lips blue, and an anxious expression about the eyes. The capillaries of the face were markedly dilated. He was normal so far as murmurs were concerned; lungs somewhat emphysematous.

Ether was administered (slowly) on Allis' inhaler and for about three or four minutes, patient took the anesthetic well. Color remained about the same, there was no attempt at vomiting, no struggling, and the pulse, while of fair volume and strength, became more rapid. After about five minutes from the time the anesthetic was commenced the patient became more cyanosed and asked to be allowed to sit up, which request was granted. Consciousness had not been affected by the ether up to this point, pupillary reflexes were present, and rigidity and voluntary movements still remained.

Patient's condition became worse, and oxygen was administered; pulse became weaker and more rapid, and patient's face was a deep blue. The head was lowered and artificial respiration was resorted to. At the first pressure on the chest, fecal matter poured from the mouth and nose and continued to do so as long as artificial respiration was practised. Tracheotomy was performed, and the fecal matter poured from the larynx filling the tracheotomy tube.

The heart was audible for about ten minutes after the patient's condition became critical and artificial respiration was continued for about twenty-five minutes or from five to ten minutes after the heart became inaudible to the ear applied to the chest wall. The patient was pronounced dead and all efforts to resuscitate him were discontinued thirty minutes from the time the anesthetic was begun. Total amount of ether used was between an ounce and one and a half ounces.

Patient had had several attacks of vomiting in the morning just prior to being sent to the operating room, but at no time since he came under the writer's observation had there been any attempt at emesis, and not until artificial respirations had been instituted did fecal matter become visible.

No post-mortem examination was made and it is presumable, and indeed almost certain, that during etherization reversed peristalsis had occurred, the fecal matter had poured into the trachea, then into the lungs and the patient had literally drowned in his own excrement.

This case has points of resemblance in common with the interesting cases reported lately by Dr. Andrews, of Chicago. There is no doubt in my mind but that the ether had benumbed the sensibility of the throat, and the acrid fecal matter had not excited any attempts at expulsion by vomiting, but had poured from the pharynx into the trachea in a rapid and uncontrollable lethal torrent. The fearful suddenness with which this death-dealing Niagara acts, makes it impossible to hope for effect from any treatment, as is shown by a study of this and Dr. Andrews' cases.

The suggestion of Dr. Andrews concerning the use of local anesthesia in intestinal obstruction operations is a good one, and cannot fail of appreciation by those who have been so unfortunate as to have been eye-witnesses to a case such as the above.

Dr. Andrews in his summary remarks that "we have no evidence that it (flooding of the air passages by fecal vomit) can occur during consciousness even *in extremis*."

The case just reported presents this noteworthy peculiarity, that the patient was apparently fully conscious and was able to articulate intelligibly and intelligently, but yet gave no sign of impending death from fecal drowning.

The Destruction of Sugar in the Organism.—That all the tissues of the body have the power of splitting up the sugar-molecule was discovered by J. Arnheim and A. Rosenbaum (Hoppe-Seyler's Zeitsch., Dec. 19, 1903). This power varies with the different tissues, and is greatest when the tissue of the pancreas is combined with another tissue. The means by which this process of glycolysis is brought about is not yet known.

A HISTORY OF SALIVA, ITS PHYSIOLOGY, CHEMISTRY AND PATHOLOGY.*

BY HAROLD M. HAYS, A.B.,
OF NEW YORK.

The action of saliva in health and disease is not a new subject. During all ages it has been more or less the object of contemplation and research, not because its study was more enticing than many others but because of the probability that its secretion was vital and necessary to the maintenance and welfare of the body.

At the time of Hippocrates, little was known about physiology. We read in his writings that the glands were spongy viscera, destined to secrete humidity to the surrounding parts.[1] But as the physicians of that time were given up to the speculations of transcendental philosophy and its application to life, there were various theories as to the source of the secretion of the saliva and its action. By many of the old philosophers and physicians, the salivary fluid was supposed to be excrementitious in its nature and the terms saliva and sputum were used synonymously. It was natural for them to suppose that the saliva had no other function.[2]

The contents of the saliva at that time, and for a great many years for that matter, were never determined by chemical means. As all glands were "destined to secrete humidity," the salivary glands followed the rule of all the others. However, it must be admitted that physical and speculative characteristics were given to it. It was thought to be composed solely of water with a little salt and spirit. Variations from these three proximal ingredients were given by many, as Koeperus, Neuter, Hoffman, Viridetus, Lentelus, et al. The speculative notions entertained by many of the older authors concerning the impregnation of saliva by animal spirits seemed to be due to the occasional occurrence in it of carbonic acid and atmospheric air which appeared to make it bubble and froth. The discordant opinions concerning its further composition were either the result of idle speculation or of the examination of the fluid having been made both in its morbid as well as in its healthy condition.[3]

The association of physiology, pathology and therapeutics, in ancient and medieval times was little known. Although saliva, as a physiological entity was of little consequence, the fluid (as in many parts of the world until recent times), was used as a therapeutic agent. There is little doubt, however, that whatever therapeutic value it had was in the efficacy of its arousing faith as to its healing properties.

As an external application, saliva has been universally in great repute for affections of the eyes. When Vespasian visited Alexandria, an inhabitant of the city besought him to spit upon his eyes for the restoration of his sight. We are told that the remedy was successful. In various affections of the eyelids, it was recommended by Vereducius.[4] To remove the pits of smallpox, its employment had been suggested by Doloeus.[5] To heal ulcers and cure warts, it had been recommended by Nuck. And, lastly, it had often been advised to add saliva to ointments to facilitate their absorption, for what purpose we know not.

As a bland and soothing agent, saliva has always been used. It seems to be the natural prevocative of man and animals to use it for emollient purposes. For example where the mucous membrane of the lips has become excoriated, it appears to have a soothing effect. In cuts, in the sting of bees, in the bites of poisonous insects or reptiles, saliva has often been applied to the injured part and has mitigated the intensity of the pain and soreness.*

One interesting incident in the supposed therapy of ancient times, has been handed down to us. In the old Grecian arena, at the Olympian games, etc., the saliva was often used to strengthen the fists of the pugilists. Either the man himself spat into his own hands or saliva was rubbed into them. It was thought at that time that there was a stimulating action of the saliva exercised over the part treated, and so the hands would become more limber and more impervious to injury. This ancient custom still exists among the fist-fighters of to-day. The young ruffian on the street corner who is about to enter into combat, considers it a natural thing to spit into his hands and "limber them up" before he enters into battle. It is but a good example of the process of evolution and the transmission of unconscious acts by heredity.

A true function of the value of saliva was not thought of up through the middle of the Dark Ages. Even Galen gave no anatomical description of the glands. He maintained that the saliva was transmitted to the mouth by particular *veins*. The idea was never suggested to him to attribute to these organs the special function of preparing a useful fluid. In fact, he considered the salivary glands as receptacles for an excrementitious humor of the emunctory vessels. The preparation of a fluid in these glands, was perhaps thought to be a secondary affair in the function of the gland.[1]

After the time of Galen, the same ideas held forth until the middle of the eighteenth century. Chemistry was then beginning to come to the foreground and many men spent much thought and time on the examination of the saliva as to its chemical constituents, its variations in health and disease and lastly as to its physiological importance. It was known, for example, as early as 1788, that if saliva be heated, it not uncommonly acquires an acidity in a few moments.[6] Berzelius, a Swedish chemist (1790), first discovered and described ptyalin, which at that time was not known as a specific enzyme and was never isolated, being considered as a portion of the albuminous product of the saliva. Trivaranus (Biologie

* Department of Physiological Chemistry, College of Physicians and Surgeons, New York City.

* It has often been noted in laboratory experiments on dogs that the saliva which the dogs lick on their wounds often acts as a gelatinous covering, thus protecting the wound almost as well as if collodion had been put on. This fact will often obviate the necessity of putting on any bandage at all, especially if the wound is small.

565) first observed the blood-red color saliva acquires on the addition of a persalt of iron. He believed it to be produced by a constituent denominated by Winterl, "acide du sang" and which Porret afterward proved to be hydrosulphocyanic acid. The observations of Porret were subsequently confirmed by Gmelin and later by Ure. It was found that sulpho-cyanogen occurred in human saliva, in sheep, in some dogs and horses, chemically combined with potassium. The proportion varied, being augmented by local conditions, stimulation of the salivary glands, as in smoking, chewing, etc. It was also supposed to be increased by the internal use of prussic acid, salts of cyanogen and remarkably so by the use of sulphur.[2] It was discovered by Leuchs, about 1828, that saliva has the property of converting starch into sugar. After this, many experiments were made to substantiate the doctrines already brought forth and to observe the action of saliva on the stomach. Spallanzini and Reamur introduced food, previously deposited in perforated tubes into the stomachs of different animals; they found that when the food was moistened with saliva, it digested more quickly than when moistened with pure water.[7]

We thus see that with the steady advance of science up to the year 1842, the saliva was beginning to be appreciated as a separate and individual part of the human organism. Experiments were done to justify its digestive powers; its reaction was ascertained in various ways; its influence and its chemical constituents in disease, were tested and so its study grew steadily.

To sum up the main things that were thought about saliva in 1841, I shall quote the conclusions of Dr. Wright, published in the *Lancet* of that year: (1) Saliva has the power of modifying, and, to a certain extent, of digesting vegetable and animal substances. (2) It has a more powerful action on the vegetable than on the animal matter. (3) The healthy digestive action of saliva is always attended with the evolution of lactic acid. (4) Filtration or boiling, diminishes the digestive powers of the saliva but does not destroy them. (5) Exposure of the saliva to atmospheric air, for a moderate length of time, does not materially weaken its digestive powers; but they are enfeebled in the ratio of the putrescence of the fluid. (6) Oxygen gas assists the digestive action of the secretion, but is not essential to it. Carbonic acid gas impairs this action in a mild degree, and hydrogen and nitrogen gases weaken it very considerably. (7) *Acids and alkalis, added to saliva, diminish or destroy its digestive properties.* (8) The presence of saliva in the stomach is essential to healthy digestion. (9) The digestive action of saliva is not possessed in any efficient degree by animal mucus, acid, alkali or alkaline salts.

Physiology.—As in all secretions of the body, the experiments have been made both upon man and animals. The general tendency has been, not to find any new substances, but to study the variations in constituents and the variation in action of these constituents during the physiological life. Thus, for example, saliva has been studied under the action of alcohol, ether and other substances.[8] Again, the quantitative variations in alkalinity and digestive power have been studied.[9]

The real action may be divided into three classes: (1) Its action in mastication; (2) its action in deglutition; (3) its action in digestion.

The masticatory action of saliva is a simple physical process and probably was observed hundreds of years ago. The food seems to be lubricated, as it were, and thus is formed into boli, which can the more easily be chewed. A proof that the saliva is important in mastication is observed from the fact that saliva is more copious in those creatures whose food requires continued mastication. "In ruminating animals, accordingly, the salivary glands are numerous and of great size, while at the same time they are so situated that the play of the muscles in the act of rumination communicates to them a proportionate stimulus. In those again who do not masticate, but swallow their food entire, there is scarcely any salivary secretion, and the glands appropriated to it are very small." [10]

The deglutition action also is more or less physical and is designed to act upon those foodstuffs which in themselves contain little free water, to act as a lubricant. Thus, for example, it is found that an ordinary cracker can be swallowed with difficulty unless there is sufficient admixture of saliva to allow it to glide along the walls of the esophagus.

Naturally, it is now admitted that the principal action of saliva is its aid in digestion. But as late as 1840, the only way this was known was by the fact that when saliva was absent, there was a marked deterioration in nutrition and digestion. "Though I have been unable, from experimental inquiry, to discover in saliva any physiological activity, yet I have observed that its alteration or its absence is invariably characteristic of a depraved condition of the saliva; and, as I shall hereafter endeavor to prove, the various morbid states of this fluid being representative of disease in the system or in its secretion, the examination of the ptyalin may be advantageously suggested as an addition to our other means of diagnosis" [2] (Wright).

The digestive action of the saliva may be considered as (1) that in the buccal cavity, and (2) that in the stomach.

The action of saliva on starch was first discovered by Leuchs and afterward verified by Schwann. Leuchs digested in some acidulated saliva for twenty-four hours a certain quantity of boiled starch, then filtered the fluid, and found that iodine produced in it no change of color. Having neutralized it and evaporated it to dryness, he obtained from the residue, by means of alcohol, a considerable quantity of sugar which he recognized by its taste as well as by its property of fermenting yeast. The part of the residue which the alcohol did not take up, consisted of the salivary matter of the saliva, in part altered in

its properties, and of starch changed to a substance resembling gum, which with the iodine did not strike the blue color which characterizes starch.[7]

The action of saliva upon starchy products has been studied up to the present day. The principal action seems to be in changing the polysaccharide to a more soluble form as follows:

Starch
|
Soluble starch
/ ———maltose
Erythrodextrin
/ ———maltose
Achroodextrin
/ ———maltose
a. achroodextrin
b. achroodextrin.

But the amylolytic power of saliva is not constant. There are decided changes according to the time of day it is secreted, the character of the food eaten, whether disease is present or whether the patient is possessed of emotional disturbance as will be cited later on. Hofbrauer shows that there is a distinct fluctuation at various periods of the day. For example, the amylolytic power is greater before breakfast than after the morning meal.[11] This is confirmed by the observations of Chittenden and Richards.[9] "It would appear that saliva secreted after a period of glandular inactivity, as before breakfast, is ordinarily possessed of greater amylolytic power than the secretion obtained after eating. Before and after dinner, however, the difference in amylolytic power is less pronounced, a fact which might be expected of the short period of recuperation between the breakfast and dinner and because of the more or less constant stimulation of the salivary glands during the waking hours." These changes in digestive power seem to be due primarily to a greater intensity of the enzyme ptyalin.

The action of saliva is not especially manifest on forms of food other than starch but there is no doubt that other kinds of food alter its secretion and intensity. In this connection may be mentioned the intake of great quantities of food of any kind which need mastication, and the eating and drinking of stimulating articles of diet, such as pepper, salt, alcohol, gin, whisky, etc. All of these substances change the character of the saliva in alkalinity, amylolytic power and amount of solid matter.*

The action of saliva in the stomach is practically a minor one. That which is not combined with the starch enters the stomach in its own form and exercises its action principally by its alkalinity. At first it helps to neutralize some of the hydrochloric acid at meal time; and in the intervals, it acts as a stimulant to the mucous membrane of the stomach, the same as any alkaline substance will. There is no doubt, however, that there is a distinct relation between the secretion of saliva and the gastric digestion, probably due to some influence of the nervous mechanism because of the intimate relations between the two secretory centers in the medulla. "From a number of cases we see that a debilitated or depraved function of the stomach is apt to be associated with a defective action of the salivary glands."[3]

Among some observers, the quantity of alkalinity which the saliva gives to the gastric juice is of great consequence, probably because of the stimulation of the gastric cells. "The habit of smoking after a full meal is capable of excellent physiological significance. If a person spits much (as in smoking a pipe) the acidity of the stomach has not as great a chance to become neutralized. The alkaline saliva is wasted instead of serving a useful purpose. And, conversely, if a man sit down to a good cigar or pipe after dinner and swallow the saliva which the tobacco occasions, the stomach will find itself aided in its digestion and an equilibrium of digestion will be established. So, also, the indigestion consequent upon sleeping after dinner, or after a hearty supper, is chiefly owing to a diminished or suspended secretion of the saliva." *Cum grano salis!*

There is no doubt that there are baneful influences from too frequent or abundant spitting, partly due to the change in the stomach. Dyspepsia and all its concomitants are often the result. Dr. Wright says that he once spat 250 drams of saliva in one week, often having to spit right after dinner. In seven days, he lost eleven pounds and was much weakened and emaciated.[3] When any secretions are thus abnormally taken from the body, the like result follows.

As the ingestion of too little saliva into the stomach seems to have a deteriorating effect, so the swallowing of too great an amount will be a source of discomfort and uneasiness and cause a change in the gastric digestion. Too little saliva causes a bad effect *during* and *right after* meals; too great an amount exercises its effects *between* meals. In people who are habitually large eaters, the salivary secretion is generally very abundant. This is also observable in children and in healthy young adults. Such subjects are usually intolerant of hunger, and when fasting longer than common, are apt to suffer severely from nausea, flatulence and pain in the stomach. "An increased flow of saliva occurs always in long fasting, perhaps due to psychical or reflex influences. The desire for food being urgent, the salivary fluid is correspondingly increased, and of course the fluid is generally swallowed for want of something better. This at length becomes a source of uneasiness; some pain may be felt; there are flatulence, nausea and eructations. If food be not taken, the saliva is discharged in the clear limpid state in which it was swallowed. In such cases the appetite is often not fully restored except by the repose of the patient or by a stimulant. They are said to fast until they are sick." We seldom see this action in invalids where the secretions are not so active, nor do we find this in people who never have a strong sensation of hunger. Perhaps, if a person is going to take a walk

* An excellent table to illustrate this point may be found in the American Journal of Physiology, Vol. 1, page 475.

before breakfast, a little crust of bread will ward off the feeling of discomfort, because enough secretion is given to the stomach, whereas in fasting the saliva is often diminished. If we are to act on this same principle, we may thus account for the beneficial effects of smoking or chewing tobacco or the chewing of gum in allaying nausea and hunger.

The action of the nervous system upon the salivary secretion is most profound. But one is not prone to regard this in physiological states of the system. There seems to be no doubt that all the secretions of the body are more or less reflexly or directly governed by terminal end fibers in secretory cells. For example, in anxiety, in a fit of anger, in profound grief, in derangements of the nervous system in such diseases as locomotor ataxia and brain tumors, the secretions of the body are inhibited or augmented. The salivary secretion follows the general rule. A reflex augmentation may be incited by the sight or smell of food; a diminution may be brought about by fear or a cachetic state. By experiment, also, it has been shown that saliva exerts a marked influence *upon* the nervous system. It has been found in the injection of saliva into the arteries or veins of an animal, that spasms, convulsions and coma will often result. One might think that the direct cause of this was the same action as any foreign body would exert. But it was found that if other fluids were injected, no such results followed. This proves that the action of saliva on the central nervous system is one solely due to some inherent power of its own.

"The salivary secretion is immediately influenced by the operation of the mind; the sight of a delicious repast to a hungry man is not more effectual in promoting it, than is the operation of fear and anxiety in repressing it. Whence we are told to believe that the Hindoo ordeal by rice may have occasionally assisted in the ends of justice. This ordeal was conducted in the following manner: The persons suspected of any crime, being assembled in a ring, a certain portion of dried rice was given to each, which they were directed to chew for some moments, and then to turn it out of their mouths on the leaves or bark of a tree. Those who were capable of returning it in a bulky form were at once acquitted, while those from whose mouths it came out dry were pronounced guilty."

A medical man tells of a patient who was of a very nervous irritable temperament, who had the idea that she was the subject of enlarged liver; and, because of this, requested that she be given mercurial inunction in order to become salivated. As she could not take internal preparations, because of a disordered digestion, she was given a little common lard, darkened with charcoal, with which she very conscientiously anointed herself every night for about a week. At the end of that time she was as profusely salivated as if mercury had been given.*

Other examples of the action of the central nervous system on saliva are unnecessary. The purpose of this brief résumé, is but to recall the fact that the secretion of saliva is certainly a complex affair.

Physiological Chemistry.—The ordinary qualitative analysis of saliva may be found in any text-book. In simple terms it may be expressed thus:

Water 99.5 per cent.	Solids 0.5 per cent.
Organic.	Inorganic.
Mucin	Salts of Na, K, Mg, Ca.
Serum albumin	KSCn
Serum globulin	Traces of SO_4, etc.
Cells.	
Bacteria	
Spores	
Food débris.	

The quantitative composition certainly varies with individual observers and in individual subjects, according to the time of day the saliva is taken, the amount secreted, the food eaten, etc. The average amount calculated by Bidder and Schmidt is 1,500 grms.[3] for the twenty-four hours. The quantity of secretion may be equal in one hour to eight to fourteen times the weight of the glands, "and there is probably no gland in the entire body, as far as we know at present—the kidneys not excepted—whose ability of secretion under physiological conditions equals that of the salivary glands." [14] *

As was seen before, the amount of the saliva may be directly proportionate to its solid constituents or not. Saliva is always denser after a meal than during fasting and the old impression used to be that it was denser in the evening than in the earlier part of the day. This has been ably disproved by Chittenden and Richards.[9]

Aside from all this, the principal things of interest are the amylolytic power and the alkalinity of the saliva and whether the amylolytic power is increased or diminished in changes in alkalinity. We have already discussed the amylolytic power. Let us turn to its reaction.

Saliva is now known to be alkaline in reaction but it was not always thought to be so. Hoffman, years ago, thought it to be acid.[15] So also thought Viridetus, Lentilius, Heinsius and Dionysius. Others found it to be acid after fasting a certain length of time. The saliva of dogs is generally alkaline; oftentimes that of sheep and pigs is acid; but monkeys in confinement are more subject to it than other animals.[2]

It has several times been observed in dogs that the salivary secretion, which was previously strongly alkaline, became feebly alkaline, or neutral *post coitum*. The saliva of man and animals is generally increased in alkalinity by abstaining from sexual indulgence and conversely.[3]

The relation of amylolytic powers to akalinity is even now a subject of numerous investigations. According to Hammarsten, its action is greatest when neutral.[14] According to Chittenden and

* A number of similar actions of the mind are well illustrated in Hack Tuke's "Influence of the Mind over the Body."

* A comparative table of quantitative estimation of the saliva is well seen in Hammarsten's "Physiological Chemistry."

Smith, it is most active when feebly acid.[16] "Experiments on the diastatic action of the saliva under various conditions have recalled the fact that human mixed saliva in the presence of an equal volume of gastric juice, containing 0.5 per cent. hydrochloric acid, is capable of forming from a given quantity of starch a much larger amount of sugar than the same quantity of it alone can produce under a like degree of dilution, this being the more remarkable when it is remembered that the same percentage of acid itself greatly retards the diastatic action." [8] From a number of experiments by Chittenden and Richards, it is seen that the variations in amylolytic power are not dependent upon the amount of alkaline salts; but that, more likely, the alkaline salts are increased when there is a greater degree of amylolysis, showing a higher degree of concentration of the enzyme.

But the alkalinity varies at different periods of the day, under different conditions and with different individuals. It has been found to be fairly constant for a given period of the day in the same individual.[9] However, the variation in alkalinity is very slight, in any event. It is greater in the saliva after a night's rest. Before and after dinner, there is little difference.[9] It would seem from this that there was a constant equation between the alkalinity and the amylolysis, for they both seem to vary at the same time. Yet the reaction, probably is due more to the concentration of the fluid at these times, than anything else.

Pathology.—The physiology of saliva has received far more attention than its pathology. And rightly so. For in the various diseases of the human individual, where pathological states of the saliva have existed, there have been far better indications of the disease in the urine, in the facies of the patient and in other symptoms. Yet to the experimental pathologist and chemist, pathological states of the saliva have their interest; for it may be that there is an altered state in certain latent diseases where no other indication of the disease may be found In certain cases of jaundice for example, the saliva is colored; but so is the skin, the conjunctivæ, etc., so that diagnosis from this source is not needed. In a case of ascites reported, urea was found in the saliva, but urea was also found in the sweat and in the ascitic fluid when this was withdrawn; so this did not aid in diagnosis. So, in other diseases, foreign substances are found constituting a part of a general diathesis. However, there are some diseases where the quantity of the saliva and its quality are changed, as in the ptyalism of mercurial poisoning. And again, one can hardly think that if serious experimental research is adopted to determine the variations of the saliva in a number of cases, we shall not be able to diagnosticate several important diseases. Hoffman stated years ago that "the state and kind of most diseases can more readily be learnt from an inspection of the saliva than from an examination of the blood or urine." So believed Pausa, Poterus and Baglivi. Of course, in the light of our present knowledge concerning the value of the examination of the blood or urine, this is a little far-fetched but it indicates the point. "An intimate acquaintance with the pathology of saliva is an important item in the recognition or relief of disease; and, as will be anticipated, a restoration of the secretion to the normal state of purity, is a most efficient means of contributing to the healthiness and activity of the other functions which are necessary to the sustenance of animal life." [3]

Various pathological states of the salivary secretion have long been known to exist. *Deficiency* of the secretion is often associated with a debilitated or depraved function of the stomach and in wasting fevers; it may also be associated with obstruction to some of the salivary glands by calculi. As we have stated before, it may be secondary to an inhibitory action caused by grief, passion, fear or anxiety. *Excited* or *increased* salivation may be caused by a hyperacidity or superacidity of the gastric juice. This variation is often seen in cases of hypochondriacal and melancholic patients. Hoffman speaks of the abundant salivation of these patients.[17] M. Rayer relates the case of a hypochondrical female, twenty-four years old, who for many years was attacked at intervals of thirty, forty or fifty days, with a profuse salivation which lasted from thirty-six to forty-eight hours. The quantity of saliva discharged in twenty-four hours amounted to several pints.[18] Of the excited salivation of mercurial poisoning, we have already spoken.

Fatty saliva is often associated with a fat necrosis due to some obstruction to the circulation. *Sweet* saliva is an accompaniment of diabetes mellitus. *Albuminous* saliva is exceedingly uncommon. Dr. Cranston Chrales mentions that in a young man he found, just as Seminola had done, some albumin in the perspiration and saliva as well as in the urine.[19] *Bilious* saliva is found in severe cases of jaundice due to cholecystitis, cholelithiasis, or carcinoma of the head of the pancreas—in fact in any disease where jaundice is found elsewhere. Oftentimes the saliva is not colored, but on chemical examination is found to contain bile salts and bile acids. *Bloody* saliva is of no consequence, as it is usually due to hemorrhage in the nasopharynx or from an ulcer of the stomach where the other symptoms are of much more importance. The only point is to differentiate it from a hemoptysis.

Uric acid may be found in the saliva or a uric acid diathesis may alter the saliva. "When uric acid headache is present and the urine is scanty, the mouth also tends to become dry or sticky and the saliva is scanty; and when the headache has been cured by acids, opium, iodides or any of the drugs which clear uric acid out of the blood—not only is there a diuresis but the saliva also becomes relatively profuse." [20]

In a case of ascites, reported in the *Lancet* of 1841, urea was detected in the saliva. I shall quote the case at length, as it tends to demonstrate the excretory equilibrium which the body maintains.

Female, thirty-nine years old, regular and temperate in habits. Large abdomen; pain in kidneys; passed water without diffculty but the quantity seldom exceeded two to three ounces in twenty-four hours; secretion was pale and nearly colorless, but without a trace of albumin; spec. grav., 1.026; tongue furred; saliva acid; bowels constipated; appetite capricious. On tapping, three gallons of fluid were removed from the abdomen. About three weeks later, there was pain in the cheeks and profuse salivation. The saliva discharged was of a pale chocolate color, slightly ammoniacal in odor, strongly alkaline in reaction and, according to the patient, very disagreeable in taste. The quantity discharged in the first twelve hours amounted to 14½ ounces. A pint and a half of this was examined and was found to contain ten grains of urea. The next day the saliva amounted to twenty-three ounces and the next day to twenty-five. Then the amount gradually decreased down to the time of death. The kidneys were increasing in activity every day. "To the deposit of urea in the abdominal cavity in one instance and the discharge by the salivary glands in another, may be referred the patient's freedom from cerebral disturbance throughout the entire course of the disease. The evacuation of the abdominal cavity for a time suspended the function that was going on, but the kidneys still being incapable of their natural amount of exercise, an increased salivary discharge resulted, and in this vicarious action, urea again found an exit. As the kidneys resumed their activity, the morbid excitement of the salivary glands diminished."

This example, one of the clearest in the literature, shows one of nature's economical processes whereby one set of organs is brought into play for the elimination of foreign substances, when the proper organs are out of order.

Conclusion.—From a perusal of these pages, it will be seen that there are many interesting points in connection with saliva, some of which have only been worked out "in embryo." As through the lapse of time we observe the wonderful improvement in technic and the broadening out of ideals, we see that the work on saliva has also broadened its field. Our forefathers in research have made many mistakes which we have in part corrected, but they had not discovered everything and so it remains to us of the present day to evolve new schemes and to attempt new methods of diagnosis. An indication of this kind is in working on tuberculous saliva which the writer is now doing. Another indication of just as profound value is in trying to detect urea in the saliva in cases of eclampsia. I have no doubt that many readers will have thought of other possibilities. The urine nowadays is examined for everything; and yet it is only a few years that this has been the case. Hardly anyone denies that its examination helps decidedly in diagnosis. It is only in the last two or three decades that we have examined the stomach contents of patients and yet its examination is of paramount importance. So we may find that in the future the examination of the saliva will also play a decided part in the diagnostic arsenal.

SURGERY OF THE GALL-BLADDER AND DUCTS.*

BY JOHN F. ERDMANN, M.D.,

OF NEW YORK;

CLINICAL PROFESSOR OF SURGERY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

When speaking of cholecystitis at the present date, the surgeon does not of necessity mean that only an inflammatory condition of this viscus is present, but assumes that the term be taken in its fuller clinical significance that of an inflammatory condition of the gall-bladder possibly complicated with stones, etc., and as such I will consider this portion of the paper.

It is necessary to eliminate from our minds the old idea that attacks of pain and periods of inflammation of this viscus are due to the presence of stones, as, not only has this been proven in an experimental sense, but we are meeting constantly with cases of marked inflammatory conditions with all the symptoms of stone in which no stones are present upon operating. Naturally for a period of time this practical demonstration was clouded by the haze of the question of presence of calculi at a former time, and that they were expelled before operative interference was undertaken. In more recent years experimental research with controls showed that pain typical of that supposed to be produced by expulsion of stones, was or could be due to efforts at expulsion of the contents of an inflamed, or distended and inflamed gall-bladder, no matter whether these contents were bile, mucus or pus, stones, or a mixture of all these.

This fact being brought so forcibly to our knowledge has done more for the surgery of cholecystitis than years of medical observation and washing of feces for the presence of stones, so that now we operate not only for the relief of cholelithiasis, but also, and quite frequently, for empyema of the gall-bladder, hydrops, etc.

With the foregoing facts it must be admitted that the presence of stone or stones in the gall-bladder, etc., is a marked predisposing factor in producing cholecystitis. We can but admit that the constant or even occasional rubbing of the mucous membrane of the gall-bladder by stone

* Read before the Passaic City Medical Society of New Jersey, December 10, 1903.

may eventually produce a desquamation at some point or points, and then the active microorganism finds its proper bed and medium for propagation.

Experimental research has demonstrated that a sterile body introduced into the gall-bladder will not produce a stone, but that the injection into a sterile gall-bladder of certain microorganisms, such as the typhoid or colon bacilli will be followed by their formation. Further, it is proven at almost every operation when cultures are taken of the contents of the gall-bladder, and microscopical and bacteriological study of the stones is made that one or the other of these bacilli are present in both stone and fluid contents.

Clinically it is also known that those who have suffered from typhoid are more prone to have this disease than those who have not, and that sufferers from typhoid are very prone to have acute cholecystitis as one of the complications. A rarer form of complication is that of perforation of the gall-bladder. (See John F. Erdmann, *Annals of Surgery*, June, 1903.)

How these bacilli enter the gall-bladder to produce the inflammatory condition has been ably demonstrated by Dr. Lartigan, of Columbia College, who maintains that the blood current is responsible for their presence in the liver, and from that organ they are taken up by the bile ducts and find a repository in the gall-bladder. There they may remain inactive for years. Recently I operated upon a case in which the bladder contained 33 stones and clear bile. Culture showed bacillus of typhoid but no other microorganism. This patient, five years before had fever in Cuba, and began to have his first gall-bladder symptoms one year before the operation.

It is admitted also, that microorganisms may possibly enter the gall-bladder and ducts by means of the Vaterian papilla from the intestines.

For the proper consideration of the subject we must recognize the acute and chronic conditions. We cannot ally this disease, in its dangers to appendicitis, in either of its forms, as in the former instance we have a distensible and well-nourished organ, while in the latter we have an organ not well supplied with muscle fiber nor well supplied with arterial distribution. Given a case of acute cholecystitis, we can say in its early stage that we are satisfied that neither gangrene nor perforation will occur in a few hours, nor under ordinary circumstances in a day, while in many cases of appendicitis we know that either of the above may occur in a few hours. Again, the anatomico-surgical relations of the gall-bladder are such that even if a perforation should occur, the general peritoneal cavity would not be invaded until the right pouch bounded by the gall-bladder, colon, and omentum, etc., had been invaded. In other words, with a case of acute cholecystitis we are justified in waiting for a time for the development of ultra acute symptoms or subsidence of the attack with a far greater degree of safety than in an appendicitis.

I would therefore suggest in acute cholecystitis, especially if a typhoidal complication, that a waiting plan is far better than an ultra urgency operative procedure. I do not wish by the above assertion to convey the impression that I never advocate operation in acute cholecystitis for there are cases in which the symptoms such as septic manifestations, danger of rupture or gangrene by over distention, etc., demand immediate interference when seen by the surgeon. And even in these cases it is safe to say that they have been under the observation of the family attendant for a longer period than a case of acute appendicitis would be.

The operative steps, etc., are the same for acute and chronic cholecystitis, and will be considered under the latter.

Chronic Cholecystitis.—These are the cases in which stones are most likely to be found. The history is not one of short duration but is likely to extend over a period of considerable time with evidences of exacerbation and subsidence, and demand operative interference for the relief of pain, gastric and intestinal manifestations, to prevent perforation by ulceration, etc., either into a neighboring viscus or into the general peritoneal cavity, and finally, to prevent malignant degenerations or formations.

Diagnosis.—We cannot always differentiate between cholecystitis, appendicitis, or pancreatitis, nor eliminate the presence of each or either of these latter from a cholecystitis. Far too frequently we find upon operation that the pancreas has undergone an induration or hardening due to either an acute or chronic inflammation. The same is to be emphasized with reference to the appendix. Bearing these complications or concomitant invasions in mind, it is far wiser when operating always to explore both of these structures. Should such be the case, then the removal of the appendix or drainage of the pancreatic and biliary region is demanded. Given a rigid or tense upper segment of the right rectus with pain deep seated in the region of the gall-bladder, the diagnosis, at least tentative of cholecystitis, is tenable. If in addition we have the history of pain radiating to the right shoulder and a tumor in the gall-bladder region, the diagnosis can be positive. Jaundice is never a symptom of cholecystitis except the hepatic or common ducts be obstructed either by interior or exterior means. Temperature and chills in the history point to the presence of pus either in the sac, *i.e.*, an empyema of the gall-bladder or an infection of the gall-duct, *i.e.*, cholangitis.

Operation.—The incision practised by me has always been the perpendicular one, splitting the rectus. The intercostal nerves of supply to the rectus are to be saved when possible, although their division, when necessary, does not. I am convinced, tend to any great extent to atrophy of the rectus, at least of sufficient degree to materially aid in the formation of hernia.

When necessary to lengthen the incision, this can be done by either extending it in a curve along the costal arch toward the xiphoid, or, as

has been practised recently, the cartilages of the ninth, eighth, and seventh ribs can be split and this chondro-diphragmatic flap can be raised with retractors. The T incision, cutting the fibers of the rectus transversely, although practised once by me, has never since been found necessary in all operative manipulations even including difficult duct work.

After incising the peritoneum it is necessary in some instances particularly in chronic cases to remember the enlargement of a portion of one of the lobes, known by the name of Riedel's lobe. This is very likely to be mistaken at first for the gall-bladder. The best method of finding the gall-bladder in those cases where it is not enlarged is to locate the main fissure of the liver, and then pass the fingers downward in the direction of the transverse fissure.

When the bladder is found it is my custom, when possible, to enter the foramen of Winslow with the index and middle finger of my left hand so as to have the structures of the gastro-hepatic omentum between these fingers and the thumb. Then a search can be made for stone in the duct. The next step is walling off the surrounding viscera by gauze packing so as to prevent contact infection by the contents of the bladder in case they are infected. It is not always easy in a tensely distended bladder to diagnose the presence of stone, and therefore some of the fluid may be withdrawn by means of an aspirator, or by cutting a small hole in the fundus and sponging up the leakage as fast as it appears, then clamping this hole to prevent further leakage or soiling.

At the present time it is my custom after proving the presence or absence of stone in the common duct, and packing to prevent soiling of the surrounding viscera, to cut a hole in the fundus of the bladder, grasp the edges of this incision with forceps and have my assistant sponge away the leakage. As this proceeds, traction is made upon the forceps holding the fundus, gradually pulling the bladder well out of the abdomen when possible, enlarging the incision in its wall, and examining the interior of the bladder with a finger. Should stones be present they are removed and then the disposal of the gall-bladder is considered.

Should the bladder be filled with stones, then as in Case I, no opening is made in it, but complete removal is proceeded with without delay. Should the contents be largely pus with stone or not, and no evidence by history, etc., of cholangitis, then cholecystectomy is done, provided the patient's condition admits of it. Should there be evidence that speed in operating or drainage be required, cholecystotomy is performed.

Cholecystotomy.—In doing this operation I take a purse-string suture about the edges of the opening in the gall-bladder, being careful to see that the serous membrane is inverted and tie in a tube previously wrapped in sterile gauze; a few sutures between the parietal peritoneum and the gall-bladder are taken, the original packing withdrawn. A piece of gauze drain is introduced well down into Morrison's pouch and another surrounds the gall bladder, protecting the viscera against overflow or leakage infection. These drains are removed during the first week, and the tube removed when the bile returns clear or is diminished to a very great degree. This usually occurs within four to eight days. After the tube has been removed, a small gauze drain is employed until the sinus is closed.

I have for some time ceased doing the operation of Mayo, in which he dissects out the mucous membrane previous to drainage, except in cases where adhesions are so extensive as to prevent the dissection of the gall-bladder without great danger to the surrounding structures, and feel that where we can take time to do this operation in ordinary cases that cholecystectomy should be done with drainage or not of the duct as symptoms may indicate.

Cholecystectomy.—This operation has many advantages over that of cholecystotomy, some of which are: No danger of recurrence, no necessity for secondary operation, no soiling of the patient by leakage, etc., more rapid convalescence with less danger of hernia, although this danger is slight in any type of operative procedure, complete or practically complete eradication of the infected area, etc., thereby limiting the dangers of prolonged septic discharge and the great possibility of absorption of putrid material. The operation is one of considerable ease, and when once fairly understood should be done in preference to cholecystotomy, but for the beginner in gall-bladder surgery, I would advise cholecystotomy in preference to the more radical operation.

As a preliminary to cholecystectomy I would advise, as in common duct work, the use of a sand cushion under the back in the upper lumbar region. This brings the duct attachment in closer relation to the abdominal wall and facilitates the operative task very greatly.

After the bladder is exposed an incision is made on either side through the peritoneum so as to make a flap to fill in the raw surface of the liver made by removal of the bladder. After one has found the cleavage between the serous and muscular coats the separation is readily made by the finger. Some assistance is to be gained by insinuating the finger between the cystic duct and adjacent tissues, and then working upward and toward the cystic fissure. The hemorrhage is free oozing and readily checked by packing with the exception of bleeding from the cystic artery, although this may be met with at the last of the stripping or in cutting away the bladder, and can be readily controlled by clamp and ligation. In case no drainage is decided upon, the duct is tied off and treated in any of the ways proceeded with in the stump in appendix operations. Should the case be an infected one, drainage is made down to the stump with a strip or two of gauze. In case the ducts are to be drained, we leave it, *i.e.*, the cystic, open or split it down to the common duct, then either sew with catgut a

rubber tube to the edges of the opening, packing gauze around the tube, or drain with gauze strips. The former of these methods is advised as the rubber tube carries off the flow of infected material much better for the first few days. The catgut suture is absorbed before the time for the removal of the tube is indicated.

Malignancy of the bladder calls for cholecystectomy, when possible.

Cysticotomy or incision of the cystic duct is done for impaction of stone, or for drainage of the cystic and common ducts.

Common Duct.—In addition to stone as a cause, obstruction may be due to malignancy of the duct itself or malignancy of surrounding viscera of such degree as to produce pressure sufficient to prevent the flow of bile into the intestines. Operative procedure will then depend entirely upon the extent of invasion, varying from removal of the diseased tissue to a cholecystenterostomy or allied anastomosis of the gall-bladder and intestines, provided, in these cases of bladder and intestine anastomoses, the malignancy does not prevent the flow of bile into the gall-bladder. Stone may occupy any portion of the duct. When in the course of the duct, its removal is accomplished by incising over the stone, extracting it, and then draining the ducts, or preliminary sutures may be taken over the site of the stone, cutting between the sutures, and after extraction tying them so as to close the operative wound and prevent leakage. I do not believe any procedure of suture necessary, as these wounds heal spontaneously if properly drained.

Should the stone be lodged in the mouth of the Vaterian papilla or its immediate vicinity, one or two operations may be performed, either the transduodenal operation of McBurney or the postduodenal one advocated—but not as yet done—by Dr. A. A. Berg (see *Annals of Surgery*, August, 1903, p. 275), and by C. M. Cooper, who reports three cases successfully done by his method (see *Annals of Surgery*, September, 1903, p. 480).

Should drainage of the common duct be advisable, this can be continued for as long a time as necessary by introducing a rubber tube into the common duct, sewing it there or not, and proceeding as advised in drainage of the cystic, etc.

After-treatment of these cases is often complicated in the first few days by persistent and almost uncontrollable vomiting. Bile excretion is often very much increased in the early morning hours, from 1 to 4 A.M., and is particularly disagreeable by reason of soiling of dressings and the skin irritation resulting. The flow can be markedly diminished by giving the patient a cracker or bit of toast and milk about 11 or 12 P.M., while the skin irritation is overcome by free use of an ointment of ichthyol, from ten to thirty-three per cent.

When drainage has been done flatulency with distention chiefly limited to the epigastric and umbilical region is a depressing feature. This is readily remedied by the use of 5 to 10 grains of powdered ox-gall every four hours, continued from two to four days.

A brief history of a few illustrative cases is herewith appended, showing some of the various cases of interest occurring in my practice in the past few years:

Case I.—Cholelithiasis, Cholecystectomy, Choledochotomy, etc.—Female, forty-five years of age operated upon two years ago. Gave a history of biliary colic for a number of years. In the early part of her disease the attacks were infrequent, one or two a year; they then, as time passed on, became more frequent, three or five a year. After another period of time they became as frequent as one attack a month. When seen by me in the fall of 1901 she was having attacks every few weeks, requiring from one-half to one grain of morphine at a time. Gall-stones were found in the feces. Her examination showed a woman well nourished, no jaundice, no temperature; history distinctive of gall-bladder invasion; pressure in the epigastric region produced marked pain; some tumefaction, taken for the gall-bladder. Operation.—Upon exposure of the bladder it was found to be filled with stones to such an extent that nodulations due to them could be felt all over the wall; no apparent evidence of any fluid in the bladder. Palpation of the common and cystic ducts revealed numbers of stones; hepatic duct was dilated, elongated, and also filled with stones. A complete cholecystectomy was done without opening the bladder, cysticotomy, choledochotomy and incision of the hepatic duct were done, that is, the cystic duct was cut wide open to the common duct, common duct incised, hepatic duct also cut; twenty stones, size of marrow-fat peas were extracted from these ducts; the upper portion of the common and hepatic ducts where incised were sewed, and the lower portion of the common was left open for drainage; a tube was introduced into the common duct and the wound packed with gauze. Recovery was rapid, the patient being discharged within four weeks. About one year after, she reported that she had had one attack of pain. This evidently was due to a small stone left beyond reach in the hepatic duct, although I introduced a blunt uterine curette well into the dilated hepatic duct while removing the calculi.

Case II.—Cholecystitis, Ideal Cholecystotomy.—A widow, forty-five years of age, emaciated, no jaundice; history of uneasiness, pain very slight, indigestion, gastric and intestinal manifestations, some flatus; sense of weight in right half of abdomen; one or two attacks only in a period of four years, the pain at which times was not sufficient to require an anodyne, but was relieved by applications of heat, etc. Palpation revealed a tumor extending well into the right lumbar region; tumor was fixed and was suspected by a number of consultants to be a malignant growth of the ascending colon. I was of the opinion that it was gall-bladder disease, whether malignant or enlarged by distention not known. Exploration

revealed enlarged gall-bladder six inches long, congested and filled with bile and also containing a stone 1½ inch long by an inch in its transverse diameter. The gall-bladder was sponged out, the stone extracted from its point of impaction in the cystic duct; incision in gall-bladder closed by two rows of suture, a small strip of gauze placed in apposition with the line of suture, and the abdominal incision closed up to the point of the drain; drainage removed in forty-eight hours. Patient made prompt recovery, and has had no further attacks.

This is the only case in which I have done the ideal operation of cholecystotomy, and do not feel at the present date that we are justified in doing the ideal operation. Had I this case to do again, I should, without question, do a cholecystectomy, as it was a typical case for such an operation.

Case III.—Cholelithiasis, Cholecystotomy, Cysticotomy and Choledochotomy.—A man, thirty-five years of age, history of an injury thirteen years before by a plank falling and striking him in the region of the gall-bladder. Within a few months following this injury he had typical attacks of biliary colic; this was followed by numerous attacks, increasing in frequency and intensity; up to the time at which I saw him. He had lost very greatly in weight, and would often have attacks of jaundice, although not accompanying every attack of biliary colic. A diagnosis of cholelithiasis invading the common duct was made. Operation was extremely difficult owing to the adhesions which masked any possibility of differentiating the viscera in this region. The gall-bladder was finally found, contracted and filled with stones; the ducts markedly dilated and all filled with stones, over three hundred stones being removed from the gall-bladder and ducts. A lithotomy scoop was passed into the ducts a distance of four inches, scooping out at each maneuver small quantities of calculi; a drain was placed in and the wound packed. The flow of bile was quite excessive and with it numerous small stones were discharged each day. This washing out of calculi by the bile continued for over two weeks, sometimes as high as forty and fifty being picked out of the dressings. Owing to the dissection of the adhesions a fistula formed in the transverse colon. Successive attempts at closure were unsuccessful, but at the time of discharge only a small sinus was left. It was rather interesting to note the rapid increase in flesh the patient made, even while in the hospital. Within a period of three or four weeks he gained twenty pounds. Within a period of six months after his operation, the patient had gained fifty pounds.

The benefit of the drain of the duct in this instance, although no septic process was present, is readily seen by the fact of the discharge of small calculi which were washed out of the hepatic and biliary ducts of the liver.

Case IV.—Acute Pancreatitis, Cholelithiasis, Cholecystotomy.—A woman fifty-two years of age; had been a sufferer from attacks of supposed biliary colic for several years; when seen by me was suffering from epigastric pain; pulse 120; slight elevation of temperature; peculiar dyspnea; mild degree of cyanosis; patient's general condition bad. Diagnosis of acute cholecystitis; abdominal section made, and upon cutting through the peritoneum, a large quantity of fluid resembling beef tea was expelled; small white patches were seen all over the omentum and mesentery; gall-bladder distended and filled with stones. Diagnosis changed to acute pancreatitis with fat necrosis and cholelithiasis. Gall-bladder opened hurriedly; two thousand three hundred and fifty stones extracted; patient died in forty-eight hours. Examination of the specimen of the omentum showed typical fat necrosis.

Cases V. and VI.—Ultra Acute Cholecystitis, Cholecystotomy.—I have recently been called upon to operate upon two cases of ultra acute cholecystitis, both occurring in people under forty, one a trained nurse of the age of twenty-eight, and one a priest at the age of thirty-five. In the nurse eighteen very small stones, rough mulberry in character, were found in a distended gall-bladder; no pus evident macroscopically. In the priest three very small smooth stones were found, the gall-bladder also distended and no pus macroscopically found. The pulse and temperature in both these cases were practically alike, the temperature rising rapidly to 104° F. in the first twelve hours, pulse varying from 120 to 132; intense pain; tenderness in the region of the gall-bladder; general expression bad. Both these cases were operated upon in emergency; cholecystotomy done in each case; ultra acute symptoms subsided in twelve hours after the operation.

Case VII.—Cholecystitis, Pregnancy Five and One-half Months, Cholecystectomy.—Patient thirty-eight years of age; history of gall-bladder invasion, dating from a period of four years or more when seen by me; had been diagnosed by some other physicians as floating kidney. When seen by me with family physician, had a temperature of 101⅗° F., pulse 126; woman fairly well nourished; tumor in the right hypochondriac region about the size of an orange; exquisitely sensitive; cutaneous hyperesthesia marked; uterus on a line with the umbilicus. Refused operation; reported next day not any better; again advised operation; not accepted; reported on the second day following, condition worse; operation accepted. Upon exposure, gall-bladder was found to be 9½ inches long from the cystic duct to fundus; fundus was four inches across; bladder covered with numerous necrotic areas; large quantity of fluid resembling beef tea; omentum walling off this region; stone found impacted in the mouth of the cystic duct; cystic and common ducts palpated with negative result; gall-bladder released from adhesions and opened with a knife; large quantity of fluid expelled; edges of the incision grasped with forceps and the gall-bladder brought well up on the abdominal wall; the remainder of the fluid was sponged out and a stone,

which was 2½ inches long, 1½ inch through its diameter, weighing 550 grains was removed from the mouth of the cystic duct. Cholecystectomy was done, accompanied by profuse oozing, readily checked by means of gauze packing; a ligature was tied about the cystic duct; gall-bladder excised; stump of cystic touched with carbolic acid; large gauze drain inserted down to the duct, another small one into Morrison's pouch; drainage removed on the seventh day; patient miscarried twelve hours after the operation; discharged from the hospital in the middle of the third week with a small sinus left. It was interesting to note in this case the rapidity of repair; the small incision (four inches long) through which a cholecystectomy was done, and the fact that although a number of necrotic spots were evident upon the gall-bladder surface, no slough or active suppuration took place. Had a cholecystotomy been done, the patient would not have been discharged short of five or seven weeks, and an immense amount of slough and suppurating of the diseased gall-bladder would of necessity have followed.

Case VIII.—Cholelithiasis, Stone in Common Duct, Choledochotomy.—Female, about thirty-three years old, suffered from biliary colic for a number of years; lost in weight over forty pounds in four years, although at the present time is a woman fairly well nourished; appearance of jaundice; diagnosis of common duct invasion. Operation revealed stone in the middle of common duct. This was one of the easiest exposures of the common duct that I have ever had or ever seen. Patient had a marked diastasis of the recti muscles, evidently due to a pregnancy. This made a particularly lax abdominal wall; the duct itself could be raised from its posterior attachments very easily. No attempt at preliminary suturing was done in this operation; the duct was cut directly over the site of stone; stone extracted about the size of a filbert; drain put in down to the point of the incised duct; abdomen closed up to the point of the drain; patient discharged from hospital the third week. At the expiration of eight months the patient had gained twenty pounds.

THE REGULATION OF THE DURATION OF EXPOSURE AND THE DISTANCE FROM THE TUBE IN X-RAY THERAPY.*

BY ENNION G. WILLIAMS, M.D.,
OF RICHMOND, VA.

The first question an X-ray operator has to determine is at what distance shall the tube be placed from the patient and what shall be the duration of the exposure.

In the literature on this subject there is an especial want of observation on these practical points. One can readily see why such details have not been given. The component parts of different machines and tubes vary. Every outfit has its several variable and controlling factors, different combinations of which bring about a different quality of X-light with its corresponding effectiveness. A great deal has to be learned by experiment and experience with each outfit. Fairly definite directions, however, can be given in regard to these factors even if they be only general and relative. If we fix the other controlling factors and make them constant we can with a fair degree of accuracy prescribe the treatment measured in time and distance.

Besides the latter two we recognize in every outfit as controlling and variable factors the degree of vacuum of the tube, the resistance in the circuit and the quantity of electricity (ampèrage). The penetration of the light is dependent upon the degree of vacuum and the resistance in the circuit and the intensity is dependent upon the quantity of electricity.

The degree of vacuum and the resistance can be regulated and made constant factors by means of the vacuum and spark-gap regulators. The volume of electricity is governed by the speed of the plates in the static machine and in the coil by the speed of the interrupter and the current supplied to the primary. These can be governed by the regulators provided for the purpose.

If we render constant the penetrating quality and the intensity of the light we need then consider only the time and distance.

The accompanying table is given to show the relative effect at different distances based upon the rule that applies to all forms of radiant energy that the intensity varies inversely as the square of the distance.

Distance.	Relative intensity.			Safety limits.
2	1	1,000	25.00	2.5
4	1/4	.250	6.25	10.0
6	1/9	.111	2.77	22.5
8	1/16	.062	1.56	40.0
10	1/25	.040	1.00	62.5
12	1/36	.027	.69	90.0
14	1/49	.020	.51	122.5
16	1/64	.015	.39	160.0
18	1/81	.012	.30	202.5
20	1/100	.010	.25	250.0

In the first column are the distances at two-inch intervals. In the second are the relative intensities expressed in fractions. In the third are the same expressed in decimals. In the fourth are the relative intensities expressed in decimals taking the intensity at ten inches as unity. This column is useful, since ten inches is the average distance for an exposure; when one wishes to estimate the total amount of treatment given he can by means of this column reduce the exposures which may have been given at various distances to their equivalent at ten inches and then add the number of minutes. In the fifth column are the safety limits or the duration of time which it is safe to expose a patient without danger of a dermatitis. These figures are the result of an experience of nearly two thousand exposures personally given and by experiments in bringing about a redness of the skin by a continuous exposure. The

* Read before the Southern Surgical and Gynecological Association, held in Atlanta, Ga., December 17, 1903.

figures are about one-half of those required to produce a moderate degree of redness of the skin of the forearm with a tube of one ampère and fifteen volts with an equivalent spark-gap in the secondary circuit of five inches.

I have found the column of safety limits a valuable guide in radiographic work, and the knowledge that approximately twice the duration of these exposures under the conditions that I can regulate will produce a dermatitis has been of great value in directing the treatments.

Every outfit as well as the different combinations of the controlling factors will have its respective length of time to produce a dermatitis. Every operator should therefore at first try to determine this point. He can thus avoid undesired and unlooked-for results and foretell by several days the effects that occur.

The fear of unexpected and harmful results has been too much exaggerated. There is no more reason why we should fear the danger from the rays than from strychnine. Both are powerful therapeutic agents capable of regulation. They should be prescribed and used within their limits and according to the indications.

The treatment of deep growths requires especial attention to the time and distance. The difficulty in reaching them has been the danger of injuring the superficial tissues before the deep growths are affected. Now we know it is not necessary to bring about a necrotic inflammation to destroy a cancer. If we can have the rays penetrate the tissues with moderate uniformity we can then hope to destroy the deep growths. The closer the part is to the tube the greater is the difference in the effect upon the skin and the part beneath. For instance, suppose we have a growth four inches from the surface and the surface four inches from the anode: According to our table the effect on the skin would be represented by .250 and that on the growth .062, or a difference of .188. Of course this does not take into consideration the loss of intensity due to penetrating the tissues. If the surface of the skin be placed at eight inches the growth will be at twelve; the relative effects will be .062 and .027, or a difference of .035. With the skin at sixteen inches and the growth at twenty the relative effects are .015 and .010, with a difference of .005. We thus see that the further the part is from the tube the less is the difference between the effect on the skin and the part beneath. We should therefore place the part far off and make due compensation by increasing the duration of exposure directly as the square of the distance, or by referring to the table one can determine the duration for the exposure. My rule is not to expose in ten days more than the number of minutes required to produce a dermatitis. As this point is approached the exposures are shorter and at longer intervals in order to watch developments. As soon as the redness is reached and its degree determined, the treatment can be continued and directed according to the indications.

I realize that in the above remarks there are vulnerable points, but it is a tendency toward a more rational technic based upon a physical law. The sooner we bring our technic under fixed laws the more uniform and more successful will be our results.

SEA-BATHING IN SOME FORMS OF SKIN DISEASES.*

BY R. ABRAHAMS, M.D.,

OF NEW YORK;

ADJUNCT DERMATOLOGIST TO THE LEBANON HOSPITAL, INSTRUCTOR IN PHYSICAL DIAGNOSIS POST-GRADUATE SCHOOL AND HOSPITAL, AND DISTRICT PHYSICIAN MT. SINAI HOSPITAL, NEW YORK CITY.

Sea-bathing, whether used as a luxury or employed as a remedy, is limited to a fraction of the year. This being the case, expensive trials and experiments with this measure in any form of skin affections can hardly be undertaken with success. This reason probably accounts for the remarkable paucity of literature on the subject. For diligent research and personal inquiry failed to elicit any information on the influence of sea-bathing in diseases of the skin.

My experience with this method of treating some forms of skin diseases extends but over two summers, yet the success attained in each case sufficiently warrants the suggesting, if not the recommending, of sea-bathing as a reliable and curative agent in certain skin affections.

This paper deals briefly with forms of cutaneous diseases which have manifested a willingness, as it were, to yield to the influence of sea-bathing. There are others which appear to be equally amenable to the same agent, but the observations regarding them are as yet immature.

My list embraces the following diseases: Pityriasis versicolor, six cases; Herpes tonsurans maculosus et squamosus, three cases; Chronic eczema, five cases; Pruritus senilis, two cases.

To avoid unnecessary repetition one case of each form of the diseases mentioned will be cited for illustration.

Case of pityriasis versicolor: The victim was a young man, a lawyer, twenty-five years old. He was afflicted with that disease for several years. The blotches extended on the front and back of the trunk, neck and arms. Both his ability to secure the best advice and his anxiety to get rid of the disfigurement, which prompted him to carry out every suggested measure, failed to cure him. Two summers ago the patient was advised sea-bathing. After taking a dozen baths the disgusting affection disappeared.

Now I am well aware that pityriasis versicolor is far from being the opprobrium of dermatology. Indeed some authors consider it a one-night-cure disease. Still, cases come up from time to time which defy all care and the very best of remedies. They will persist in returning in spite of your best efforts. They are like the will-o'-the-wisp.

*Read before the New York State Medical Ass'n, October 20, 1903.

Sea-bathing in these stubborn forms is a remedy par excellence.

But more signal success has been achieved in the treatment of a skin disease which occurs less frequently and is of much longer duration, even under treatment, than the one previously considered. I refer to acute general Herpes tonsurans maculosus et squamosus.

Let me cite one typical case, history and treatment. A girl, aged twelve years, had an attack of this disease in the beginning of June this year. The eruption extended over the trunk and the extremities. First, there appeared small, red, flat papules. Then, in two days, the papules turned into small patches. Both papules and patches were covered with oily scales. The exfoliation began at the center of each path, and gradually ended at the periphery, leaving the point from which it started pale and depressed. Shortly, typical rings formed from which occurrence and peculiarity the disease is commonly known as ringworm of the body. The itching was extremely intense and distressing.

Sea-bathing was suggested for no other reason than pure experiment. The child took ten baths in ten days and got rid of her trouble. In this case there was observed a total absence from all forms of medication—internally or externally. Sea-bathing alone received the credit for the cure.

It may be well to mention that both of these affections of the skin are parasitic in origin. Pityriasis versicolor is eminently so and is universally acknowledged to be caused by the fungus *Microsporon furfur*. Herpes tonsurans maculosus is caused by the *Trichophyton tonsurans;* this causation, however, is not so universally accepted; some maintain that it is an external expression of gastro-intestinal disturbance, as was lately argued in an extremely interesting and elaborate paper by my friend Dr. Ludwig Weiss.

The mycotic origin of these diseases is alluded to because of the apprehension that some might claim that sea-water containing, as it does, iodine, bromine and other antiparasitic elements and compounds which have the reputation, on terra firma, as being inimical to the life and growth of low forms of animal and vegetable organisms, produces the curative effect on the diseases of the skin. But the following cases will demonstrate the efficiency of sea-bathing in diseases of the skin which are positively non-mycotic.

A man, about forty-five years, suffered from gout and rheumatism for ten years. Within the last year he gradually developed dry eczematous patches on his shoulders, legs and hands and lumbar region. The induration, furrows and color of the skin were typical of chronic eczema. The itching was so intensely excruciating that both rest at day and sleep at night were unknown for many a month. Every form of treatment was employed without avail. Sea-bathing was finally recommended. Two baths a day were taken for a period of ten weeks with complete satisfaction to the sufferer. While traces of the old foe are left in slightly perceptible hardness of the affected skin and pigmentation, the troublesome affection disappeared, apparently for good.

The last case to mention in which sea-bathing was a veritable godsend was a man of seventy years, who had pruritus senilis of long standing. In his case, as in a good many other similar cases no eruption was visible nor a cause discoverable except a susceptible, irritable skin.

Daily ocean dips were advised and taken during the entire summer with the result of freeing the homo senilis from his horrible pruritus.

Now for comparison and comment: Assuming that the therapeutic virtue of sea-bathing rests in the chemical composition of the sea water, I directed a few of my patients who suffered from diseases of the skin above mentioned to bathe in tanks filled with ocean water such as are found in some of the regular Russian and Turkish bathing establishments—tanks of water which are considered "as fresh as the sea but safer." I must confess the utter failure to obtain any appreciable results. In view of this, the comment and conclusion inevitably are that bathing in the sea, besides the inherent properties of the medicated water, derives additional value from some other sources which are, I believe, first the longer immersion which is possible because it is more agreeable in the sea; second, the pounding of the billows which rubs the water more thoroughly into the skin; third, the exposure to the sun in the interval of the dips, which dries the solids of the water into the skin, and lastly, the rolling on the sand of the beach which wonderfully helps to remove scales and other pathological débris from the skin, and thus affords the water a better chance to penetrate the affected areas.

These reasonings may sound far fetched, yet a harmless theory is better than none.

43 St. Mark's Place.

PERICARDITIS; WITH THE REPORT OF CASES.*

BY GEORGE P. PAUL, M.D.,
OF TROY, N. Y.

The object of this paper is not for the purpose of presenting new points but to distinctly emphasize three points: First, the insidious development of pericarditis, and how frequently it is overlooked unless particularly sought for. Second, that pericarditis of a severe type may develop during the course of a very mild pneumonia. Third, the difficulty of distinguishing obliterative pericarditis from acute general tuberculosis involving the serous membranes.

Pericarditis may be classified as primary or idiopathic and secondary. This latter form occurs most frequently after acute articular rheumatism, septic processes rank next to rheumatism, in tuberculosis it may occur as a part of the gen-

* Read before the Medical Society of Troy, N.Y., and Vicinity.

eral involvement of the serous membranes or succeed extensive pulmonary lesions. Among other causes may be placed acute eruptive fevers, Bright's disease, diabetes, scurvy, etc.

Pathologically, pericarditis may be classified as dry and moist. It generally begins as the dry form, in which there is at first a redness of the membrane which soon becomes lusterless and is later more or less covered by an exudate of fibrin. The amount of fibrin may be small or great. The moist form is as a rule an advanced stage of the dry form. The exudate may be serous, sanguineous or purulent depending on the etiology. The hemorrhagic form occurs in tuberculosis and in cancer. The disease may terminate in one of several ways: (1) It may end in resolution by absorption of the exudate: (2) it may become chronic and dense bands of adhesions form between the two layers of the pericardium and also between the pericardium and the surrounding structures. (3) The purulent form may rupture into the esophagus, pleuræ, stomach or even into a bronchus. The pus may become inspissated and later a deposit of lime salts ensue.

Pericarditis, as has already been said, is very often overlooked on account of its insidious onset. Very often no subjective symptoms are present at the onset of the disease and the diagnosis can be made only after a very careful physical examination. If during the course of an acute infectious disease the rhythm of the pulse becomes altered, or its rate increases out of proportion to the rise of temperature, or the heart's action becomes tumultuous, or a sudden rise of temperature takes place, a careful physical examination of the heart should be made. On the other hand, the onset of pericarditis may be marked by severe pain, which may be anginal in character. The form with effusion may present characteristic symptoms as altered cardiac rhythm, precordial distress, aphonia dyspnea, dysphagia, cough and other symptoms of pressure, and often a very active delirium.

In the majority of cases the diagnosis is made from the physical signs. In the dry form there is one sign which is of diagnostic importance, and that is the pericardial friction rub which may be single or a to-and-fro rub and is intensified by pressure on the stethoscope. If it is single it is generally systolic in time.

The friction rub of pericarditis may be confused with the pleural friction, the pleuropericardial friction or an organic heart murmur. The friction of dry pleurisy disappears on holding the breath while the pericardial friction rub is not altered. From a pleuropericardial friction it is more difficult to differentiate it, as both are present during the cessation of respiration. The pleuropericardial friction becomes more intense during inspiration and less during expiration, while the pericardial friction is not altered. From an organic heart murmur it is differentiated by the time and transmission of the murmur and the character of the pulse. Another important sign which is often present is the friction fremitus.

In pericarditis with effusion the signs are more numerous, but vary with the amount of fluid: *Inspection.*—There may be bulging of the precordium and complete or partial obliteration of the intercostal spaces. The apical impulse if seen is feeble and is often seen upward and to the left. *Palpation.*—The apical impulse is feeble or absent. *Percussion.*—The cardiac area of dulness is increased in size. The area of dulness is triangular in outline with its base below and its apex directed toward the junction of the third left rib and the margin of the sternum.

If the effusion is large there may be detected in the left infrascapular region, an area of dulness due to compression of the lung. *Auscultation.*—The friction sound heard in the first stage may entirely disappear at this time. The heart sounds are feeble and distant, the first sound may lose its muscular element and resemble the second sound. Bronchial breathing, due to compression of the lung, may be present in the left infrascapular region corresponding to the above mentioned area of dulness.

The diagnosis of pericarditis with effusion may be confused with dilatation of the heart. In the latter, the apical impulse is generally visible and wavy. The area of dulness is not triangular. The cardiac sounds are sharp, clear and not distant.

Case I.—This patient entered the hospital as one of probable typhoid fever, which disease its symptoms strongly suggested, on January 28, 1903; is a male, twenty years of age, boiler maker by occupation, from whom the following anamnesis was obtained. Family history is perfectly negative in regard to anything that has bearing on his present condition. He had gonorrhea two years ago and has never been ill otherwise until the present illness. Present illness began five days before admission, with pain in the abdomen, severe frontal headache, loss of appetite, looseness of the bowels and a slight cough. As these symptoms resembled typhoid fever, the Widal and Ehrlich's diazo reactions were performed and both were negative. The blood examination showed hemoglobin 70 per cent., red corpuscles 3,500,000, and white cells 17,000 per cm. (The hyperleucocytosis directed our attention to some infectious process, thus showing the value of blood examinations.) The urine was negative. The sputum was mucopurulent, blood stained and contained pus cells and the diplococci of pneumonia.

Physical Examination.—The patient was well developed and of good musculature. The lungs were negative except for a small area of dulness at the base of the left lung posteriorly. Over this area, vocal fremitus and resonance were increased and fine crepitant râles and bronchovesicular breathing were heard. Heart sounds and cardiac dulness normal. The pulse was of good character. Liver was overlapped above by vesiculotympanitic note and the liver dulness extended slightly below the free border of the ribs. Spleen was slightly enlarged. Abdomen slightly

distended and tympanitic. Other organs, reflexes and sensations were normal.

January 31, four days after admission, the onset of the pericarditis was detected by the presence of a to-and-fro friction rub heard in the third left intercostal space and was not transmitted from the precordium nor altered by the cessation of respiration.

February 9, ten days after the onset of the pericarditis, the following signs were detected: *Percussion.*—The cardiac area of dulness began at the third left rib, at the level of the fifth rib it extended 19 cms. to the left of the midsternal line. The apical impulse was within this area of dulness. *Ausculation.*—The cardiac sounds were feeble and distant. The respiratory murmur and voice sounds were absent in the precordium. Previous to the advent of these signs there was no change in the subjective or objective symptoms except that the patient's countenance became dusky and anxious. At the time of appearance of the friction the pulse rose to 120 with no change in temperature or respirations, but during the formation of the effusion the temperature was 104° F., the pulse 130 and the respirations 40. In the latter part of the illness the pulse became irregular. The fluid disappeared to a considerable degree but soon returned and the patient is still under observation at the hospital.

Case II.—Male, aged twenty-two years, born in Turkey, buttonholer by occupation. *Family History.*—Father and some other relatives died of consumption. Mother alive and well. Patient has always been well until the present illness, which began in March, 1902, when, following a severe "cold" he became short of breath on exertion, had pain in the epigastrium and back, and had a severe cough. He entered the Samaritan Hospital in April, 1902, and was treated until June when he left the hospital much improved. During his presence in the hospital his chest was aspirated a number of times, the character of the fluid being serosanguineous. The patient remained in a fairly comfortable condition until two weeks before his last admission, November 29, 1902, when he again became quite short of breath and coughed considerably.

Physical Examination.—Patient is of medium stature, scanty musculature, pale, poorly nourished. The lower intercostal spaces are effaced especially on the left side, recession of the supra- and infraclavicular spaces, respiratory movements are greatly restricted especially on the left side. Vocal fremitus is absent below the level of the third rib and exaggerated above. *Percussion.*—Anteriorly, absolute dulness below the level of the third rib, the upper limit of dulness reaches a higher point in the axillæ. Posteriorly, the dulness extends from one inch below the angles of the scapulæ to the free border of the ribs. Posteriorly there is on the right side a small area of increased vocal fremitus and resonance, bronchovesicular breathing is also heard here. *Auscultation.*—Respiratory murmur is harsh above the level of the third rib and lost below. Vocal resonance is marked above and decreased below the level of the third rib. Apical impulse neither visible nor palpable. Heart sounds are feeble with reduplication of the first sound. Cardiac dulness obscured by the effusion. Pulse is small and rapid. Liver and spleen are normal. In the latter part of November fluid began to collect in the abdomen and ascites developed to a considerable degree. A little later the hands, feet, legs and thighs became quite edematous. About six weeks later a pericardial rub was detected but it disappeared in the course of a week or two. The cardiac sounds became feebler and distant and the pulse irregular. Dyspnea and cough became very annoying at times but were relieved after removal of part of the effusion. The right pleural sac was tapped twice but no fluid was found. The left pleural sac was tapped eleven times, the total amount of fluid removed was 20 pints. The abdomen was tapped once and 20 ounces of fluid removed. The fluid returned very soon after removal. The fluid was serosanguineous and under microscopical examination no bacteria were found. The sputum has been repeatedly examined but no tubercle bacilli were present. Blood examination showed 7,500 white cells per cmm. The lymphocytes slightly exceeded the normal number. The urine was negative.

This latter case is of interest because of the liability of confusing it with the disease to which F. Pick, of Prague, called the attention of the medical profession, and to which he gave the name of pseudo cirrhosis of the liver due to obliterative pericarditis. The principal symptoms of this disease are ascites, dyspnea, slight edema of the extremities, cyanosis, enlargement of the liver and the local signs of pericarditis. In differentiating this case from Pick's disease several factors must be considered. The effusion in the chest, the ascites and the general anasarca made their appearance before the pericardium was affected; while in Pick's disease the pericarditis is the primary cause of the accumulations of fluid. The liver was not enlarged as in obliterative pericarditis. The fluid drawn from the abdomen was inflammatory in character, *i.e.*, sanguineous and not simply serous as in transudations. The edema of the extremities was early in the course of the disease and was very great; in Pick's disease the anasarca is late, and, as a rule not very great.

The process having started some time ago in the lung and later involving the pleuræ together with the character of the fluid withdrawn and the loss of weight, etc., point toward the tuberculous process.

In conclusion it will be well to mention a few of the important signs of adherent chronic pericarditis: (1) A systolic retraction in the region of the apex. (2) The sign described by Broadbent, which is a distinct systolic retraction of the chest wall in the region of the eleventh and twelfth ribs on the left side. (3) Friedreich's sign, a collapse of the cervical veins during diastole, and, according to Kussmaul, a swelling

of the cervical veins during inspiration. (4) The pulsus paradoxus is significant of adherent pericarditis or rather of the dilatation which follows. The pulse becomes small and feeble during inspiration, due to traction on the adhesions during the inspiratory expansion of the lungs. As these bands are drawn upon it causes a constriction of the vessels of the mediastinum; thus resulting in a small feeble pulse wave during inspiration.

INDICATORS IN GASTRIC ANALYSIS, WITH SPECIAL REFERENCE TO TROPEOLIN OO.

BY A. L. BENEDICT, A.M., M.D.,
OF BUFFALO;
CONSULTANT IN DIGESTIVE DISEASES, CITY HOSPITAL FOR WOMEN AND RIVERSIDE HOSPITALS.

My attention has recently been called to this matter, partly by a study of various practical problems in physiological chemistry, and partly by various articles which have appeared on the subject in the medical literature.

In spite of being an originator of a method of gastric analysis dealing directly with proteid digestion, it seems to me that we must all admit that the most important detail in the chemic analysis of chyme is the acidity and, especially, hydrochloric acidity.

Two methods of measuring hydrochloric acid by titration have received the attention of the profession. In one, the investigandum is treated with decinormal sodium hydroxid solution with an indicator in the capsule; in the other, a drop of investigandum is removed from time to time during the titration and is tested qualitatively for free mineral acid. The latter method is very tedious and almost necessarily requires a preliminary titration by the former method but is, I believe, far more accurate. One of two reagents may be employed—the phloroglucin-vanillin and the resorcin-saccharose solution. Either one of these when heated short of charring, drop for drop of investigandum, yields a brilliant crimson ring in the presence of a mineral acid. Personally, I have not used the phloroglucin-vanillin test for about ten years, as the resorcin-saccharose reagent is more stable and while said to be a trifle less delicate, it will detect one part of hydrochloric acid in 4-5,000 of diluent. In other words, its delicacy is sufficient for practical purposes. In experimenting with dilutions of pure hydrochloric acid, we can determine the end reaction between crimson and dull yellow within two or three degrees of the titration. In experimenting with chyme, there is a pretty sharp change from crimson to rose and from this to dull yellow. The rose color probably indicates a freeing, by heat, of hydrochloric acid in organic combination or the action of fermentation acids or both.

In gastric analysis and similar work, the term degree or per cent. of acidity refers to an amount of decinormal monobasic alkali solution equal to one per cent. of the investigandum and as the latter is usually 10 c.c., a degree corresponds to $^1/_{10}$ of 1 c.c. in the burette.

In the method of titration with an indicator in the capsule with the investigandum, dimethylamido-azobenzol is commonly employed, although, formerly, Congo red, tropeolin OO, and even benzopurpurin and various other dyes, were employed. A series of experiments, reported last year in *American Medicine,* have convinced me that dimethyl (those of us who have become familiar with it, use its first name alone for the sake of brevity) gives too high results by about 15 degrees, if we take as the end reaction, the final color change, but that we must read the free hydrochloric acid at the point where the bright cherry-red changes to orange and this point can be corroborated by noting also the final discharge of color and making the subtraction of 15 degrees.

Total acidity is indicated most conveniently by using phenolphthalein as an indicator. This reaction is sharp within a few degrees of gradual development of color and is considered fairly accurate by chemists. In states of euchlorhydria (25 to 50 degrees of hydrochloric acid), the total acidity will vary between 3 and 2 times the free hydrochloric acidity. In hyperchlorhydria, the total acidity will range between 2 and 1½ times the free hydrochloric.

Between free hydrochloric acid and total acidity, we have fermentation acids, acid salts—principally phosphates—and combined hydrochloric acidity. Nothing definite is known about combinations of proteid and fermentation acids. In accordance with the general principle that a strong acid supplants a weak one, hydrochloric acid will be neutralized before the vegetable and fatty acids. The principal organic acids found in chyme are acetic, lactic and butyric, but various others occur. These cannot be readily separated, either quantitatively or qualitatively. On account of the antiseptic action of hydrochloric acid, however, large quantities of organic acids probably never develop in a stomach with regularly high hydrochloric acidity, although, if the eu- or hyperchlorhydria is merely temporary or if there is ischochymia, there may be considerable organic acidity in the presence of a relatively high hydrochloric acidity.

How shall we separate the various acidities intermediate between free hydrochloric acid and the total reaction with phenolphthalein? Aside from investigations on the incinerated chyme, two methods have been proposed. One depends upon the following reaction: Proteid chloride plus sodium tungstate equals sodium chloride plus proteid tungstate, the last being insoluble and neutral to phenolphthalein, whereas proteid chloride (combined hydrochloric acid) is acid to this indicator. As I pointed out in the report previously mentioned, this statement is only measurably true. While a marked fall in acidity by phenolphthalein occurs after adding neutral sodium tungstate to the investigandum, while we are reading the burette, we observe that the pink color has become discharged, we recover the color by adding a few drops more of the alkali

solution and the same phenomenon is repeated and, if we let the test stand for a few hours, we can gradually run the acidity up to almost exactly the same reading as before we added the tungstate. Personally, I am by no means convinced that the diminution in the immediate total acidity correctly indicates combined hydrochloric acid—aside from the matter of phosphates to be considered later—but, if we use this method at all, we must read at the first transient change of color with phenolphthalein.

The other method for estimating combined hydrochloric acid is based on the hypothesis that alizarin changes from olive to purple when we have saturated everything but combined hydrochloric acid. Thus, by subtracting the dimethyl from the alizarin end-point, we get organic and phosphatic acidity while, by subtracting the latter from the phenolphthalein end-point, we get combined hydrochloric acid. But, very commonly, we find by this method, a relatively enormous amount of combined hydrochloric acid when the free HCl is low and when everything points to a deficiency of hydrochloric secretion and digestion in general. I have even seen instances in which the final color change with dimethyl occurred at a point beyond alizarin. Dr. G. H. A. Clowes, of Buffalo, has published in the *American Journal of Pharmacy* for June, 1903, an interesting article* on the estimation of phosphates in chyme depending upon the fact that the alizarin end-point occurs at the transition from H_3PO_4 to NaH_2PO_4 and the phenolphthalein end-point at the next transition from NaH_2PO_4 to Na_2HPO_4, while Na_3PO_4 is formed only in an excess of alkali. However, it is obvious that phosphates as well as combined hydrochloric acid lie between the alizarin and phenolphthalein end-points and, in many cases, as when phosphates are administered medicinally, this disturbing factor is very important.

The general consensus of opinion with regard to tritrations of chyme, is that the estimation of free hydrochloric acid is approximate, the estimation of total acidicity quite exact, and that the alizarin or sodium tungstate methods are very inexact, though better than nothing. This sentiment is significant, as some clinicians are disposed to draw very fine lines with titrations and, in particular, Dr. Knapp's interesting article, in the MEDICAL NEWS of Nov. 14, 1903, is entitled "Why Not Absolute Precision in Chyme Analysis?" Even incineration methods are not regarded as absolutely precise without regard to the general fallibility of mankind, and titration methods must be accepted as merely approximate, though usually sufficiently accurate for diagnosis and treatment.

A very practical consideration is the amount of investigandum to be used for each test and what tests are to be omitted if the chyme is scanty. The old statement that 20 to 30 c.c. is the normal amount of residue one hour after a standard test breakfast, must have been due to inadequate methods of extraction. Within the last year or two, I have almost discarded expression and my roller tube-stripper and now rely on a bulb syringe with strong walls—such as is commonly sold to keep the population within limits. By alternate suction and moderate distention of the stomach with air, while the tube is held at various levels, one can remove almost every drop of chyme and can tell by the sound and the patency of the tube, when the extraction is complete. By this method, 40 to 100 c.c. may be taken as normal limits, one hour after a meal of 50 grams of bread and butter and 250 c.c. of water, or thereabouts.

Whenever possible, all manipulations should be upon the filtered chyme. It was formerly stated that the minute particles of unfiltered chyme held acid and therefore results were minified by working with filtrate. I believe this observation is mainly due to the fact that with unfiltered investigandum, one cannot tell just when he has reached an end reaction and thus has to add an excess. Sometimes the reverse is true. For instance, in vomited matter after a meal of brown bread, etc., the dimethyl test apparently yielded an unmeasurable trace of free hydrochloric acid. The filtrate showed 27 degrees (to the orange point).

As a rule, when very little material is available, the dimethyl test and the phenolphthalein test should be used in succession. If 10 c.c. cannot be obtained—as in some cases of mucous gastritis with little secretion but with good motility—the degrees are estimated from the actual reading by the rule of three. One cubic centimeter is sufficient for the tests for lactic acid, ferment activity and carbohydrates, bile, blood, etc. The next 10 c.c. I would use for my proteolysis test. (*See Journal American Medical Association*, March, 1901.) Afterward the alizarin and other tests may be applied and various experimental study may be made on cases of supersecretion.

As a rule, 10 c.c. should be used as an investigandum to avoid the experimental error which always attaches to readings made with small quantities and two or three tests made as accurately as possible, are of greater value than a number made with small quantities of chyme. There seems to be no objection to employing phenolphthalein in the same capsule with the investigandum previously used with dimethyl for the determination of free hydrochloric acid. Otherwise, the mixture of tints is liable to obscure the reaction. I have recently seen an article in which, with 5 c.c. as an investigandum, the author made four successive titrations in the same capsule, putting in one indicator after another. Such admixture of colors is too artistic for the plain digestive specialist.

Although advocating the use of dimethyl as a routine reagent for free hydrochloric acid, some of my critics, notably Dr. Knapp, in the issue of

* The article quoted is too technical for ordinary clinicians and contains one or two misprints which an inexpert chemist would not notice. The writer, with Dr. Clowes' kind permission, expects to take up this method from a clinical standpoint later.

the Medical News of November 14, 1903, have attributed to me a partisanship which I do not feel and have not tried to express. So far as I understand the chemistry of indicators, neither this nor any other can be an accurate measure of any one acid. In other words, the change of tint is a phenomenon of ionization and not at all a specific combination such as occurs in the ordinary reactions of inorganic chemistry. I was among the first clinical writers to call attention to the fact that the phloroglucin-vanillin reaction occurred with any mineral acid and not alone with hydrochloric acid and, in general, whatever indicator is used, we must expect that vegetable acids will act analogously to mineral, but to a less degree. There is no satisfactory definition of acidity, but, in a vague way, we can conceive of it as due to the position of hydrogen in a molecule. Not everything that we customarily write with an H or OH separate from the rest of the molecule, is an acid, and some substances are amphoteric, acting as acid or otherwise, according to the indicator used. Carbolic acid, for instance, acts as an acid with comparatively few indicators.

In choosing among the various indicators which mark the turning point from free acid to acid salt or organic combination, we must be guided by empiricism as to the one which produces the most distinct change and the change least influenced by weak acids. We must not overlook the fact that a delicate, limited indicator may react when a more general but less delicate indicator will not. Thus, it occasionally happens that by using benzopurpurin or Congo red and resorcin-sugar, we get the paradoxical result: "No free acid, trace of free hydrochloric acid."

The discrepant reports of different observers with regard to the virtues and faults of the various indicators used, may, perhaps, be explained by individual differences in visual physiology or, possibly, by actual histologic variations in the rods and cones. It is absurd to suppose that any one would wilfully misrepresent what he saw and almost equally absurd that one working day after day in chemic problems of the same general nature, should make a blunder of observation. We know that there are well-marked variations in tone-perception and that marked color blindness exists. It is reasonable to suppose that in dealing with delicate changes of tint, different eyes should literally see things differently.

Every little while some advocate turns up with an indicator that we have discarded several years ago. In the Medical News of January 27, 1894, I published a little scheme for the qualitative examination of chyme, including a study of some reactions with indicators. Congo reacts blue, not only with hydrochloric acid and the mineral acids generally, but with lactic, acetic and butyric acids, the last giving a turbid blue. Tropeolin OO changes from what I would call magenta to yellow, in titrating against a mineral acid, with alkali. Lactic acid restores the magenta color, but neither acetic nor butyric do so in any reasonable amount. Thus, tropeolin is a better indicator for hydrochloric acid than Congo. These statements I have just verified, in view of the contradictory statements which have been made. Tropeolin is, at least for me, an undesirable indicator because the tint with acid is obscured by a brownish or yellowish cast of the investigandum and because the end-point is difficult of detection. Using dimethyl, on the other hand, we start with an unmistakable cherry-red and, while the change to orange is a little vague, it is not more so than the single color change of tropeolin. The final color change of dimethyl is almost identical with that of tropeolin but we have two reactions as a check on each other, in the former instance. In the absence of a large amount of fermentation acidity, the dimethyl and tropeolin tests will come out about the same. With my method of noting the change from cherry to orange, for example, in one sample the total acidity was 68 degrees. By dimethyl, the hydrochloric acid was 24 degrees, the final discharge of color occurring at 36 degrees. By tropeolin the hydrochloric acid was 22 degrees. Even a considerable amount of acetic or lactic acids, or both, will not restore the cherry red of dimethyl, but will change the color back from yellow to orange.

Really, it makes comparatively little difference which of several indicators is used provided one understands that the results are approximate and reliable only for comparative purposes. With low hydrochloric acid and high fermentation acidity, the readings of the burette are very inaccurate although they indicate the principles of therapeutics clearly enough. Whenever it is necessary to have accurate tests made, the chyme must be incinerated.

PHYSIOLOGICAL AND CLINICAL ASPECTS OF HYDROTHERAPY WITH ITS SPECIAL REFERENCE TO THE TREATMENT OF PYSCHOSES.*

BY R. D. BAKER, M.D.,
OF MORRIS PLAINS, N. J.;
ASSISTANT PHYSICIAN, NEW JERSEY STATE HOSPITAL, MORRIS PLAINS, N. J.

"Hydrotherapy includes the application of water in any form, from the solid and fluid to vapor; from ice to steam, internally and externally."

The use of water in the treatment of disease is not new. Hippocrates, we read, made intelligent use of the stimulating and relaxing effects of heat and cold. Coming down through medical history we find the greatest physicians exponents of the remedial use of water. Among them are Celsus, the physician to Ovid and Fabius Maximus, Paulus Æginita in the eighth century and Van der Huyden in the twelfth century.

In 1697 a book published by an English physican named Floyer attracted the attention of the best medical minds of Germany, and adopting his

* Read before the Morristown Medical Club, October 28, 1903.

ideas water was used in the treatment of fevers and the exanthemata, but it did not become popular until the "peasant water doctor," Priessnitz, in 1840 attracted a considerable following and so spread his ideas throughout the world. To Prof. Wilhelm Winternitz, is due the credit of putting hydrotherapy upon a scientific basis. He has devoted his life to the study of its great clinical value and the scope of its application, and has thus gathered about him at Kaltenleutgebene over two thousand patients. In 1861 Ernest Brand published his results with cold baths in the treatment of typhoid fever. At this time France and Italy were also making progress in this line, though many times delayed because of the unwonted notoriety given it by lay practitioners and fanatics. This was especially so in England, where even to-day hydrotherapy is not generally popular. In the United States the early champions of hydrotherapy were Drs. Abram Jacobi, of New York City, and Hiram Corson, of Pennsylvania, followed by Dr. Simon Baruch, who has done most for its scientific progress and development, until to-day our hydriatric institutions are the best equipped in the world and in them the exact prescription of the physician may be carried out by skilled nurses. Fortunately it is not necessary to have expensive apparatus, and gratifying results may be obtained with the ordinary household toilet accessories. But technique must be zealously guarded.

Being much interested in this subject I have at the New Jersey State Hospital at Morris Plains fitted up an apparatus for douching by which the temperature and pressure could be regulated and with packs, drip-sheets, bed-baths and hot-air baths, have during the past eighteen months done considerable work among the insane, especially in melancholia, dementia præcox and psychoses of a neurasthenic and hysterical type, and I believe that no other single therapeutic measure so thoroughly tones the nervous system, so stimulates the circulatory apparatus and so satisfactorily revives organic activity.

When we think of the vast area of the skin, its structure and function, with its myriad of nerve endings, its muscular and elastic tissues, its glands and vessels, all of which are directly accessible to the effects of this agent, we may get a glimpse of its physiological action and have something of an understanding of the channels through which we may obtain more definite physiological results.

From a hydrotherapeutic standpoint we deal with the skin as a sense organ, as an excretory organ and as a heat regulator. The physical properties of water are such that the functions of the skin are directly affected by this form of application of heat and cold. From ice (32° F.) to steam (212° F.) we may use this agent with perfect mechanical control and definite knowledge of its physiological effects. By reason of its fluidity we have the advantage of being able to apply it in any desired manner, thus definitely affecting local or general areas, while the application of pressure enables us to obtain the very important mechanical irritation of the nerve-endings and other structures of the skin. It is very interesting to study the various results possible with such a flexible agent, from the awakening to the destruction of cell activity.

Primarily the action of water, no matter how used, is that of an irritant to the peripheral sensory nerve-endings, and in this reflex way affects the circulation, respiration, temperature, tissue change and secretion.

Reflex irritation of the sensory nerves affects the circulation in two ways—by acting upon the heart muscle increasing its power, and by changing the caliber and tone of the vessel walls. This applies to both topical and general applications. Cold causes a primary acceleration of the heart's action, followed by slowing and added force—increasing the heart's nutritional period in the same manner as digitalis. Heat causes a primary slowing of the heart's action, followed by acceleration.

Acting on the cutaneous vessels, both heat and cold cause a primary contraction, followed by secondary dilatation. The secondary effect of cold is dilatation, accompanied by increased volume, tension, tone and blood pressure. This is due to stimulation of the inhibitory nerves. A beautiful example of this is found in the person who goes out into the cold rain or hail; first the face is blanched by capillary contraction, after which it assumes a rosy red hue due to capillary dilatation and a more active circulation. If the stimulation is continued or excessive, however, temporary paralysis of the vessel wall follows. The secondary effect of heat is dilatation, accompanied by increased volume but decreased tone, tension and blood pressure. This is due to relaxation of the vessel walls. Therefore we may liken the effect of cold to an active congestion and that of heat to a passive congestion.

The composition of the blood is also altered. Cold causes an absolute increase of both white and red cells in the peripheral circulation, the increase of white cells being very marked. This is probably due to increased force of the circulation and altered tone of the vessels which forces the blood cells from organs in which accumulation has taken place. The maximum increase in red cells has been stated as 1,860,000, while the white cells have increased threefold, and the hemoglobin fourteen per cent. These alterations persist for from one to two hours, generally being at their height at the end of one hour. Heat causes a decrease in the number of red cells, a decrease in the percentage of hemoglobin and a slight increase in the number of white cells.

Since the heat regulating function of the skin has to do with the vessels, nerve-endings and glands, we may pass it over as the conclusions are obvious and it is by no means as important as the stimulating effects on the nervous and vascular systems.

Scientific experiment has shown that tissue change and its consequent secretion and excretion

are greatly enhanced or controlled by properly applied hydriatric procedures.

The following are a few of the most important hydriatric procedures: Simple ablution, which consists in the application of water by the hand or what not, without much friction, useful in febrile conditions and as a measure introducing more vigorous proceedings. It is apropos to say here that friction of the skin by the bare hand or the hand covered with cloth is important to the success of any hydriatric procedure. By friction, reaction is brought about, for the nerve-endings seem to need a certain amount of mechanical irritation. The non-observance of this principle is the cause of failure with those who have given up this method of treatment. It is also necessary in any hydriatric procedure to place a cold compress or turban upon the head, and this to be changed frequently.

The *half bath;* in which the water in the tub reaches just above the pelvis and is kept at a temperature of 85° to 70° F. The nurse first bathes the face and then rubs the body with one hand and with the other dashes water on the patient, who, if he is able, keeps up friction on the front of his body with his own hands. This measure is one degree further than the ablution and serves to dilate the peripheral vessels more than does the pressure-laden full bath. It should last from five to ten minutes—as the physical signs indicate—after which the patient should be rapidly dried in a previously warmed linen sheet or blanket.

Next in order for consideration is the *affusion.* In this procedure water is dashed upon the body with more volume and greater force, as from a pitcher or pail at some height. It is of short duration, but the intermittent character of the thermomechanical irritation causes a better reaction than either of the before-mentioned measures. Thus this procedure is of use when we wish more shock and stimulation, as when in the delirium of acute diseases we have a tired heart, inactive vessels and inefficient respiratory effort. The temperature of the water may be from 70° to 45° F., varying within this range in accordance with the symptoms presented.

The *sheet bath* must always command studious attention. This bath may be used in its different forms—cold rub and drip sheet—as an antipyretic, stimulating or sedative measure. In the simple cold rub the sheet wrung from water at 68° F. is wrapped about the patient snugly; first underneath and then over the arms and about the shoulders. The patient is then rubbed vigorously until warm and dry. It is customary, for the sake of better reaction, to precede this measure by previously warming the skin. This method is used for its stimulating and tonic effect. When an antipyretic action is desired, water of the same or lower temperature is poured or sprinkled upon the sheet and friction kept up until the part is again dry. This method is generally followed with the patient in bed. For a sedative action, the drip sheet is used—that is, the sheet is wrapped around the body without being wrung out and friction and slapping alternated with pouring, over the head and shoulders, water at a temperature ten degrees lower than that of the sheet. It has been found that having a patient stand in water from 100° to 90° F. aids greatly in asthenic cases.

A universally useful and valuable measure is the *wet pack.* In this a woolen blanket is placed on the previously protected bed and on this is laid a well-wrung out linen sheet. The patient, wearing a cold turban, lies upon the sheet and is wrapped snugly and so that no two skin surfaces come together. The arms are raised and one-half of the sheet is brought across the upper portion of the body and tucked along the trunk, the lower portion being placed between the legs, then the arms are brought to the sides and the remaining half of the sheet is brought over and tucked snugly about the entire body. The blanket is now wrapped firmly around the body, covering in the shoulders and the feet, great care being taken to prevent a layer of air between the blanket and the sheet. Another blanket may now be placed over the patient and tucked underneath him, accurately fitting the body curves and giving him the appearance of a mummy. The sheet should be wrung from water at a temperature of from 70° to 60° F. When it is desirable to use a higher temperature, as from 100° to 110° F., for excretory purposes, it is better to use a thin flannel blanket in place of the sheet as it more readily retains the heat. A pack of short duration—one-half to one hour—is markedly sedative, causing, after reaction has set in, muscular relaxation, cerebral anemia and oftentimes sleep. In longer duration, say one to five hours, the pack acts also as an excretory agent, the desired elimination being aided by the ingestion of several glasses of water during the pack. Cell activity is increased, resulting in combustion of autotoxines, making them soluble and easy of elimination. The skin is filled with heated blood and thus excretes more actively as the odor of the sheet testifies. The wet pack is also of use as an antipyretic measure and when this result is desired it should be frequently repeated and of short duration, as from ten to thirty minutes. It is also of great use in chronic diseases exhibiting deficient tissue change and in neuroses as a measure preliminary to the invigorating half-bath or douche. In this connection it is well to bear in mind that the wet compress is simply a miniature pack, and when used for throat or pulmonary disease or for maintaining the effect of other antipyretic and stimulating agencies, is very pleasing in its results, as will be attested by all patients to whom they have been properly applied.

The *cold full bath*, especially the Brand bath in typhoid fever, is so well known that I need not make mention of it here. The *warm full bath*, aside from its analgesic effect, it attended with highly gratifying results in the treatment of children and babies, where at a temperatue of from 100° to 95° F. and of a duration of ten minutes,

it is a most useful antipyretic and sedative. Care must always be taken to keep the bath at the prescribed temperature by adding hot water from time to time.

No article upon hydrotherapy would be in any sense complete without reference to the *douche*. In the use of the douche atmospheric pressure takes the place of direct friction and as the size and shape of the stream can be regulated as well as the temperature and pressure, it becomes a scientific method of application. The mechanical irritation of the douche is so marked that it readily overcomes the effect of cold and even makes a moderately warm spray of short duration, stimulating. Reaction is found much more active if the douche is preceded by some measure for warming the skin surface, such as the pack or hot-air bath, thus increasing the shock and rendering the stimulation consequently greater. It is also a very useful measure for restoring tone to the vessels of the skin after packs or other relaxing baths. It prevents chilling, allows the patient to take exercise in the open air and receive the benefit of deepened respiration, more active circulation and awakened metabolism. The douche should be limited to from twenty seconds to one minute, the temperature from 45° to 105° F., the pressure from fifteen to thirty pounds. In the douche, as in other hydriatric proceedings, we have a great power for evil as well as for good. The exact technic must be followed in order to assure success. Each case demands separate and careful study for the reason that by varying the temperature, pressure or duration, widely different effects are possible. It is generally necessary to educate most patients to the point where the desired measure may be used. The Scotch douche consisting of alternating streams of hot and cold water, is a measure which has found much favor as a general stimulant and as an excitant of tissue change.

The various hydriatric measures adopted in a given case will depend upon the disease, the condition of the patient and the particular result desired.

In measles, when the temperature is high—103° F.—and the nervous system shows the effect of toxemia, Dr. Baruch advises a full bath at 95° F., lowered gradually to 75° F. if necessary to obtain the desired effect; in severe cases showing delirium, stupor, muttering and restlessness the half bath at 95° F. with cold affusions at 75° F., repeated every three hours, or more often if necessary. These baths should be brief, for children having measles do not bear well the abstraction of heat.

In scarlet fever during the acutely toxic stage, practically the same procedures are recommended. If a severe nephritis is present, a full bath at 95° F., gradually cooled to 90° F., is given, lasting from five to eight minutes. The patient is then placed in a warm blanket pack for an hour or longer to promote diaphoresis, cold water being freely given to increase diuresis.

In pneumonia we deal with a very severe toxemia acting upon the nervous system and nothing so successfully combats these symptoms as properly applied hydriatric measures. In children a full bath at 95° F., with active friction, will strengthen the heart, deepen respiration, reduce the temperature and refresh the child. Those baths may be given every three hours for a temperature of 103° F. and in the meantime their effect maintained by a chest compress. If the nervous symptoms are very marked the child may be held in a half bath of 100° F., while affusions at 75° to 60° F. are used and these followed by a rapid drying with friction. A fact to be remembered, however, is that children do not bear shock nor chilling well and that the temperature of pneumonia is much more easily reduced than that of most other infections. In the pneumonia of adults Dr. Baruch does not advise baths but uses the cold chest compress at 60° F. He finds that this measure sufficiently reduces the temperature and being applied as often as indicated aids in the elimination of toxins, stimulates the heart and has a decided effect on the course of the disease. Some of the most gratifying results of hydrotherapy are obtained in the treatment of enterocolitis of young children, where as a means of overcoming the nervous exhaustion and inanition the bath or pack has come to have a value as great as in typhoid fever. Prostration and marked nervous symptoms are often rapid and severe. The skin is white and covered with clammy sweat, while the rectal temperature runs from 102° to 106° F. Here the carefully graded bath is of much value. The child should be put in a full bath at 90° F. The face and head are bathed with cold water; gentle friction is kept up and the water gradually reduced to 80° F. If more shock is desired, because of severe nervous symptoms, affusions at 60° F. may be used. The bath should not last over ten minutes. Afterward, if the temperature has been high, the child is wrapped in a sheet covered by a blanket and allowed to dry. If the temperature has been low, the child is gently dried and placed in bed. When the child has convulsions or there are objections to the baths on the part of the parents, the wet pack, from 70° to 60° F. may be used, lasting from fifteen minutes to twenty minutes and repeated if required. After this pack the patient should be laved with a cloth partially wrung out in water at 70° F. One has but to observe the pulse in such conditions become slower and regular, respiration deeper, the eyes brighter and animation and color return, to be satisfied with the value of these measures.

In my more recent work among the nervous and insane I have found the wet pack at 65° F. or the full bath at 95° to 105° F. very useful in excited cases and in insomnia, and have at present a case of mild excitement with confusion in which the patient seems to change to nearly the normal state while in the pack. She exhibits a slight temperature—100° to 101° F.—a quickened high-tension pulse—95 to 100—extensive herpes labialis, foul breath and inactive bowels, making

a perfect picture of mild toxemia. This patient is placed in a wet pack for three hours each morning and afternoon and her colon irrigated daily with normal salt solution at 110° F. She is fast losing her toxic symptoms and her excitement is daily becoming less marked.

The series of twenty-six cases which I have collected for this paper, which were all under my treatment, are classified as follows. Acute melancholia, acute melancholia with agitation, dementia præcox, hysteria, puerperal insanity.

Most prominent among their mental symptoms were depression, slowness of thought—even to apparent lack of it—little or no interest in self or surroundings, delusions of a painful nature, confusion, depression with agitation, hypochondriasis and insomnia. The most marked physical signs were lack of nervous and muscular tone, sluggish circulation with an almost constant accentuated second heart sound, no appetite, and in some instances even refusal of food, loss of weight, muddy, greasy, acne-covered skin, intestinal fermentation and constipation. The urine was scanty but showed no constant pathological change except in several cases a very slight trace of albumin, which disappeared as metabolism improved.

Where necessary in these cases, because of their weak physical condition or mental apathy, extensive enough to cause them to be kept in bed, treatment was begun with an ablution at 95° F. with active friction, the temperature being reduced 5° F. daily until 65° F. was reached. When the patient became used to this measure and reaction became ready and constant she would be given a sheet bath at a temperature of 60° F. This procedure causes more shock and prepares the patient for the vigorous stimulation of the douche. Those cases which showed depression with agitation and a run down physical condition but with a fairly active skin were given a wet pack at 65° F., lasting for from one to one and one-half hours, from which they were immediately given a general fan douche at 60° F. and twenty-five pounds pressure for twenty seconds, followed by drying with friction and exercise in the open air. Those cases exhibiting stupor, flabby, greasy, acne-covered skin and congested extremities were given the same form of pack but it was continued for from two to three hours, water being given freely during the pack, and where the kidneys were not secreting well the colon was irrigated just before the pack with normal salt solution at a temperature of 110° F. In the cases which exhibited only depression, loss of weight and lack of general muscular and nervous tone the douche alone was used. Having been accustomed if necessary by the use of the ablution and sheet bath, the patient was sprayed for one minute at a temperature of 95° F. and fifteen pounds pressure, then a fan douche was given for twenty seconds at 45° F. and twenty-five pounds pressure, followed by drying with friction and exercise in the open air. The reaction after such treatment is very marked. The respirations are deepened, the pulse is slowed and its tension reduced, the skin glows to a red hue, showing that the reaction is perfect, and the patient feels a general sense of well being.

Resulting from this treatment, the patients become brighter, more interested in things about them and in their own welfare. Agitated cases became calm, sleep was natural and dreamless, delusions were less fixed or gradually faded away and the normal mental state was often restored. The physical condition greatly improves, the appetite increases and with it the body weight—in the average of cases from ten to thirty pounds. The pulse grows strong, regular and of normal tension, the bowels regular and the skin healthy. A notable fact is the improvement in general muscular and nervous tone. The muscles take on firmness and the body curves or feature curves become round and full. This condition is so marked that on going through the wards one can detect from their facial appearance those receiving hydriatric treatment.

In connection with this treatment the patients' habits were regulated; they were given one egg in six ounces of milk every two hours during the day, besides three meals of the regular diet, if they were able to take it. After an initial purging with calomel a daily stool was obtained with tonic doses of cascara sagrada, unless intestinal fermentation was marked, when colon irrigation with water at a temperature of 110° F. was practiced, and they were made to take water internally at regular intervals as a means of aiding in the general process of elimination. Strychnine in tonic doses or the house tonic, consisting of iron, quinine and strychnine, was also given when indicated. I do not claim for hydrotherapy wonderful or miraculous results, but I firmly believe this method of treatment a most invaluable adjunct to hygienic and medicinal measures.

Of this series of cases nine recovered, twelve were greatly improved in both mental and physical health, and five, while they evidenced no mental improvement, gained in general physical health.

MEDICAL PROGRESS.

SURGERY.

Suprarenin in Surgery.—An interesting article by B. Müller (Münch. med. Woch., Feb. 2, 1904) deals with the use of suprarenal extract in major surgery. The preparation known as suprarenin was employed in almost all cases and many experiments convinced the author of the intense action of this substance upon the smaller vessels. If the mucous membrane of the mouth is moistened with a 1-1,000 solution, a pale yellow spot will result; injected into the skin of a dog in a dilution of 1-10,000 an incision could be made without the loss of a single drop of blood and a microscopic examination gave evidence of extreme vascular spasms. Laparotomies can be easily performed, but vessels more than one millimeter wide must be ligated despite the fact that their media often contracts and shuts off the

lumen after division. The pale condition of the tissues enables one to detect and avoid nerves without much trouble. In very bloody operations, such as strumectomies and amputations of the breast, suprarenin is invaluable and in the much-feared resections of the liver it must be regarded as indispensable. In order to avoid injury to the larger vessels and stopping-up of the needle, this is constructed with a blunt, closed end and two lateral openings. Care must be taken to incise within the anemic district and so that more of this lies centripetal to the knife than centrifugal. Spurting from larger vessels is avoided by manual compression of the liver, central to the cut. After-hemorrhages were never observed, since the vessels are effectually shut off by thrombi before relaxation occurs. In one case the stump was examined two days after operation. The process of healing was found absolutely normal, both macro- and microscopically and necrotic areas could not be found. Extirpation is more difficult than resection, since it is often impossible to tell how deeply one must go into the liver. In small cancer nodules or gummata the excision is wedge-shaped and the needle is introduced in the direction of the two incisions. More trouble will be experienced where the gall-bladder is to be removed, especially where the tumor has already extended upon the liver. Large vessels are encountered here in abundance, but suprarenin, by suppressing parenchymatous oozing, allows these to be seized with great ease—a point of great importance in cachectic individuals. In general it may be said that a strength of 1-1,000 to 1-2,000 has an almost instantaneous effect and is best for liver and kidneys; one part in 5 to 10,000 is sufficient for skin, fat and muscle and acts in two minutes. Up to 10 c.cm. of a 1-1,000 solution may be injected without fear of intoxication. Boiling is the most efficient means of sterilization. Weak solutions will decompose in time, but a pink solution is just as active as a colorless one. A 1-10 or 20,000 solution stimulates the heart and one cubic centimeter may even be injected into the myocardium.

New Appliances for Local Hyperemia.—The use of a suction apparatus to produce a local hyperemia has first been suggested by A. BIER (Münch. med. Woch., Feb. 9, 1904), who has devised an ingenious apparatus which can be closely fitted over any joint. As soon as the air is exhausted, the parts will redden and perspire so that the glass walls of the apparatus soon become cloudy. This suction has the same curative action as hot air; it relieves pain and renders tuberculous joints more supple without weakening those suffering from advanced anemia. Various orthopedic appliances can be placed in the apparatus to allow the patient to perform active motion with his diseased joint. The vacuum should not be so high for tuberculous joints as for chronic rheumatism, as the softened bones may be injured. The method is not applicable to acute affections. Another device recommended by the author is a hot-air apparatus with fine movable point, especially indicated in the treatment of trigeminal neuralgia. One should not become discouraged if the effect is not instantaneous, but even obstinate cases were completely relieved after daily applications during two or three months.

Report on Two Cases Operated on by Lorenz.—Two children which were operated on by Lorenz, in San Francisco in 1902, were kept under observation by H. M. SHERMAN (Jour. Am. Med. Ass'n, Feb. 27, 1904), who now publishes a report of their present condition. The plaster dressing was removed in May, 1903, six months after application and X-ray pictures taken and a careful examination made. In the first case where a boy of five years had presented an anterior dislocation, the head was found in a subcutaneous position in the outer part of Scarpa's triangle, while the trochanter was somewhere behind and internal to it. As the condition was unfavorable, the cutting operation was recommended. The latter disclosed that the capsule of the joint had been torn by the manipulations and the head of the bone was left among the muscles at the outer part of Scarpa's triangle. The head was replaced in the very shallow acetabulum, but very little capsule was left in front of it—a serious loss, as the body-weight must be carried by the capsule of the hip-joint, where an anatomic reduction cannot be made. No benefit therefore apparently resulted from the Lorenz method. The second case presented a posterior dislocation and after the cast was taken off examination showed the head to be in the outer part of Scarpa's triangle and very near the skin. No improvement had therefore taken place and the limb was probably shorter than before. Operation was not undertaken.

Case of Staphylococcus Sepsis.—An instance of this condition closely resembling typhoid fever is reported by O. NIEDNER (Deut. med. Woch., Jan. 29, 1904). As the disease was present in his associates, typhoid was diagnosed but all attempts to cultivate bacteria from the blood were negative. Delirium developed on the tenth day and on the fifteenth swelling of the parotid glands was present from which pure cultures of staphylococci were secured. Swelling then also developed over the right trochanter and elbow. The man died two days later. A month previously the patient had fallen from a ladder striking on the right side. The leg became increasingly painful and two weeks later the symptoms of typhoid developed. The parts were actively massaged. The autopsy showed changes in the intestinal lymphatic system which closely resembled those of typhoid and therefore accounted for the clinical course of the disease. The injury had induced extravasation in the right gluteus maximus muscle, which became infected through the skin and resulted in the formation of an abscess, which was situated too deeply to be discovered by palpation. The massage which was done evidently drove the infectious material into the circulation and resulted in a general infection, which rapidly became fatal.

OBSTETRICS AND GYNECOLOGY.

Early Signs of Pregnancy.—The means of diagnosing pregnancy in the early stages are none too convincing, so that any addition to our knowledge of this subject should prove interesting. H. L. E. JOHNSON (Jour. Am. Med. Ass'n, Feb. 20, 1904) describes a physical sign which he has noted in a large number of cases prior to and including the third calendar month. This sign is observed as early as the third week and consists of an intermittent softening and hardening of the vaginal portion of the cervix uteri with, in many cases, a change of color, from a pale violet to the normal pink hue, or the reverse. The alternate softening and hardening are readily detected by digital touch, while the changes in color may be seen through the speculum. These signs are probably the early manifestations of what is subsequently recognized as the intermittent contractions of the pregnant uterus and are probably due to a necessity for some change of modification in the uterine circulation incident to the nourishment and growth of the impregnated ovum through physiologic intermittent congestion of the generative system. This sign the writer has never observed in any other normal or diseased condition and reports a number of cases where the diagnosis of pregnancy was subsequently positively demonstrated where at first it was entirely unsuspected by the patient.

Modification of Porro's Operation.—Porro's operation, first undertaken in 1876, is thus described: After the uterus has been emptied as in an ordinary Cæsarean section, it is drawn out of the abdominal wound and surrounded by a wire at its lower segment. The uterus with its appendages is then cut away. William H. Horrocks (Brit. Med. Jour., Feb. 13, 1904) suggests a modification of this technic, which is upon the lines sometimes employed in the treatment of uterine fibroid. In considering the choice of operations between the Cæsarean section and Porro's operation, there are certain points in favor of the latter technic. In general one or the other of these operations is indicated when the deformity of the pelvis is so great as to render delivery without craniotomy impossible and where some tumor growing from the cervix or sacrum blocks the pelvic cavity. The question of leaving the uterus has always seemed a doubtful point, although cases have been recorded by French surgeons in which several operations have been performed upon the same woman. Of late it has been customary in performing Cæsarean section to sterilize the woman by dividing the Fallopian tubes. If this be done, the settlement of the question resolves itself into a determination as to whether more shock is produced by the removal of the uterus or by its simple section, suture and destruction of the Fallopian tubes. The technic of the author's modification is as follows: Before drawing the uterus out, it may be necessary to ligate the broad ligaments on each side and divide them. After delivery of the uterus through the wound, the peritoneum is stripped off until the neck of the uterus is reached by the finger. The uterine artery is found on each side, and a ligature thrown around it, one side only being tied. The anterior wall of the uterus is now exposed and the muscular tissue torn through with a blunt director down to the membrane. These are now opened sufficiently so as to easily remove the child. As soon as natural respiration is established, the cord is clamped, divided, and the child delivered. The cord, with the forceps is now returned into the uterine cavity, no attempt being made to remove the placenta or the membranes. A flat sponge is packed into the uterine cavity and the opening drawn together. The second ligature is now tightened and the uterus divided as low as possible. The stump is then ligatured with a double set of sutures. A sound should be passed into the bladder to determine its position before attempting to perform the uterine stump. The pelvis is now carefully dried and drainage may or may not be established through Douglas pouch. The special point in this operation is the small amount of shock due to the infinitesimal hemorrhage. The question of tightening the second ligature on the uterine artery before extracting the child is as yet not positively answered.

Puerperal Sepsis.—Even in this hour of perfect asepsis, every one is glad when the third day is over. Peter Horocks (Brit. Med Jour., Feb. 13 1904) states that a hundred years ago parturition was so often followed by fever of some kind that Nisbet defined pregnancy "as a certain inflammatory disposition of the body or nearly approaching to it." It was the rule at that time for the woman to run a temperature during the puerperium. It was looked upon as unavoidable and due to the increase in the inflammatory tendency of the blood. Inasmuch as a woman may develop a temperature after she has had a child from any cause that will produce fever in a non-pregnant woman, it becomes necessary in the first place to eliminate all possible causes other than those peculiar to that state. In other words, there is a difference between fever of the puerperium and fever in the puerperium. Strictly speaking, puerperal sepsis includes the following: (1) Puerperal fever or puerperal septicemia of the worst and generally fatal type; (2) puerperal sapremia, which is usually accompanied by an offensive discharge and which is generally recovered from; (3) puerperal pelvic cellulitis, also generally recovered from; (4) puerperal pelvic peritonitis, non-fatal usually; (5) puerperal pyemia, often a late stage of any of the preceding. Fatality depending on virulence of sepsis. (6) Phlegmasia dolens. This is now believed by many to be due to sepsis. (7) Milk fever. Inflammatory; often transient; probably septic; non-fatal.

Fibroid Disease in Five Sisters.—For a family of nine sisters to furnish five examples of fibroid disease and five of cataract is a morbid consensus of more than fleeting interest. J. MacPherson Lawrie (Brit. Med. Jour., Feb. 13, 1904) cites the history of these cases and asks what is the explanation of the peculiar predominance of the two factors—fibroids and cataracts. The pathology of fibromyomata is as little known as that of tumors in general. With regard to cataracts, it is known that impairment of nutrition of the lens increases with advancing age, and that these nutritive defects are apt to manifest themselves earlier in some families than in others. In other words, there is an inherited predisposition to that failure of repair which leads to the formation of opacities in the lens; this form of cataract, however, not being always an expression of senility. Is hereditary influence a factor in the causation of uterine fibroids? Is it possible that these two apparently dissimilar diseases are the resultant symptoms of some unknown underlying cause? The only connection between the uterus and the lens of the eye is a developmental one. The capsule of the lens originates from the same layers of the blastodern as the uterus. The lens is mainly the offspring of mesoblastic elements and is therefore in direct histological relation with muscular and vascular tissues. It seems, therefore, that the relation of cataract to fibroid in this family is either purely accidental, or else of such a profoundly obscure origin as to be extremely hypothetical. This remarkable series, however, would seem to furnish evidence to justify the suspicion that hereditary influence may be a causative factor in the pathogenesis of uterine fibroid tumors. he literature of the subject shows that the majority of writers do not ascribe any importance to the theory of hereditary transmission. The author is frank in stating that he believes this series to have its explanation in coincidence rather than in the expression of any hereditary tendency. This is a conclusion which is very tenable in view of the computation of Klob, who believed that four women in every ten have fibroids.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Neutrophile Leucocytes in Infectious Diseases.—An article containing claims of a very revolutionary character has been published by J. Arneth (Deut. med. Woch., Jan. 21, 1904), with reference to the previously accepted notions of positive and negative chemotaxis for the neutrophile leucocytes. He believes that the importance and value of leucocytosis have been misunderstood and explains the phenomenon by asserting that the process is due to the destruction of the neutrophile leucocytes, the extent of which is dependent on the degree of infection or intoxication, the resisting powers of the organism and a number of other factors. He has made an extensive investigation of leucocytosis by the aid of a new technic, which however is not revealed at present. This shows that the number of leucocytes is no criterion as to their actual normal or

abnormal condition. The condition of the nucleus is the deciding element and according to its character the leucocytes may be divided into five classes. "Cytosis" is the new term applied to these various conditions and he distinguishes between iso-, aniso-, hyper-, hypo-, and normocytosis. In infectious diseases there is an aniso-hypercytosis (equal and unequal). The investigations also show that the relations between the various forms of leucocytes are much simpler than in the old classification. It is also claimed that the neutrophile leucocytes are the producers, but not exclusively, of the antibodies. Further and more elaborate details are promised in a new book about to be published by the same author.

Tuberculous Stenosis of the Intestine.—In at least half of the cases of stricture of the gut of tuberculous origin, according to A. W. Nikoljski (Samml. klinisch. Vorträge, Dec., 1903), the condition is a secondary one. It is mostly seen between the ages of twenty and forty years, and selects principally the lower part of the ileum. Multiple stenosis is just as common as the single variety. Strictures of the intestine lasting for years are in the great majority of cases tuberculous. The diagnosis is made more probable by the presence of tuberculous foci in the individual or a history of the disease in the family. In cases of stenosis in which the etiology is not clear, the cases are best regarded as tuberculous. The treatment is resection, and success depends on resorting to this precedure early.

Modifications of the Bacillus of Koch.—Certain irregularities noted during the study of the saprophytic characters of the tubercle bacillus have led J. Ferran (Arch. Méd. Expér., Nov., 1903) to attribute them to a variability in the characters of this organism. The special pathogenic characters of the non-acid tubercle-producing bacteria are best studied before the latter have been transformed into the bacilli of Koch. During their initial virulence these germs are not at all tuberculogenic; they acquire this property only after having been acclimatized to a life within the leucocytes. The demonstration of the constant presence of the non-acid tuberculogenic bacteria in tuberculous individuals, together with their abundance and saprophytic characters, deprives the bacillus of Koch of the right to be considered as the exclusive agent in spontaneous tuberculosis in man.

The Alloxuric Bases in Aseptic Fevers.—A research of extremely practical import was undertaken by A. R. Mandel (Am. Jour. Physiol., March 1, 1904) with the view of determining the relationship between the cleavage product of the nucleoproteids contained in the cell-nucleus, which products are commonly known as alloxuric or nuclein bases and the fevers of surgical origin. This investigation was suggested by the fact that in cases of surgical lesion there is a marked increase in leucocytes and this increased leucocytosis would lead to an increased production of alloxuric bases. The author found that in such cases there is a correspondence between the quantity of alloxuric bases eliminated in the urine, and the average temperature observed at the same time. As the alloxuric bases increase in amount the quantity of uric acid diminishes and vice versa. On injecting alloxuric bases into a normal monkey there is a rise of temperature. Inasmuch as coffee contains 1-3-7 trimethylxanthin (caffeine), the author sought to determine whether drinking a large quantity of a strong decoction of coffee, produces any rise in temperature. In his own case he found this to be so. He concludes from his observations that in fevers there is a distinct relation between the rise of temperature and the appearance of certain incomplete products of cell oxidation, as shown by the excretion of the alloxuric bodies, whose source must be looked for in the circulating leucocytes or the fixed lymphoid tissue and also probably in other tissue cells. It is noted that individuals, for instance, children with good reactive ability and high leucocytosis, usually show rather high febrile temperatures. The diminution of uric acid corresponds to the increase of alloxuric bases is attributed to the lessened oxidation of the latter to uric acid. It is assumed that in a number of pathological conditions the ability of the cells of the organism to oxidize certain substances is directly interfered with, and that this probably applies to the so-called aseptic fevers, as, for instance, rise of temperature after severe operations, anesthesia, convulsions, poisons, cachexias, of various forms. It is supposed that in all these cases the temporary or more permanent injuries to the cells inhibit their oxidation ability a shorter or longer period.

THERAPEUTICS.

The Climate of Long Island.—The proximity of Long Island to the greatest center of population in this country, and the increasing use of its territory as a resort and place of residence, make valuable any study of its climatic features, so remarks W. H. Ross (Brooklyn Med. Jour., March, 1904). It is for the most part a dry sandy plain, through the center of which runs a range of hills from 100 to 400 feet in height. With only 1,682 square miles of territory it has over 250 miles of water front. The island is made up mainly of sand and gravel, with thin strata of clay at varying depths. This dry, well-drained soil modifies the climate as regards fogs, the latter being more frequent over a wet, clayey soil than over the former. During a period of ten years, the mean summer temperature was 70° F., and that of winter, 30°F. This was at Brentwood in the pine belt and about the center of the island. The mean yearly temperature was 51.8° F., compared with 45° F. for the entire State of New York, 52° F. for the city of New York, and 52.7° F. for Atlantic City. The average temperature of the island for the month of July is three degrees warmer than for neighboring Nantucket, but there is a difference in the relative humidity of 7¾ per cent. in favor of Long Island. This relatively low humidity is one of the striking features, the average for the year being 72.75 per cent., while Atlantic City has 80.5 per cent., and San Diego, 69.5 per cent., only 3 per cent. lower than that of Long Island. The amount of sunshine forms a valuable feature, the average being about three hundred days per year—more than any of the neighboring resorts. Pine forests cover a considerable area, and the yellow pitch pine is indigenous to this region. The climate of Long Island is favorable because of its low altitude in increasing functional activity of circulatory organs; in convalescence from acute diseases, and in surgical diseases to accelerate tissue changes; for all invalids who cannot bear great changes of temperature; for pulmonary tuberculosis because of its pure air, equable temperature and pine forests; for all nervous troubles requiring relaxation, particularly in insomnia due to nervousness.

Podophyllin in Anchylostomiasis.—As the result of observation and experiment, Neumann (Deut. med. Woch., Feb. 4, 1904) claims that podophyllin has a specific action on the intestinal epithelium which interferes with the attachment of the parasite. The latter are then easily dislodged by the administration by the extract of male fern after the podophyllin has been given, or the podophyllin may be alone sufficient to expel them. The action of this drug is much more pronounced than that of calomel, and it is apparently a much safer drug for the purpose.

SATURDAY, MARCH 26, 1904.

DECREASE OF FOUNDLINGS' MORTALITY.

The solution of one problem in sociology or the kindred department of sociological pathology is almost sure to introduce another one of almost as great importance as the first, though its occurrence is usually quite unanticipated. This seems to have occurred with regard to the question of infant mortality in several attempts at its improvement in late years.

It is well known that the custom of insuring the lives of children under one year of age, for the purpose of enabling parents to have enough money to bury them in case death should take place, has been followed, especially in England, where the custom was at one time very common, by a distinct increase in the proportionate mortality of insured infants as compared with the uninsured. At first it was hoped that the insurance would be a distinct benefit for family life. Poor parents almost beggar themselves and frequently starve their children for a time in order to meet the funeral expenses of a dead member of the family. This evil it was hoped life insurance on children would prevent and might even ameliorate family conditions generally by leaving less room for anxiety. In order to prevent the increase of mortality that was noted, however, strict legal regulations had to be enacted with regard to insurance on children's lives and the infantile feature of life insurance development was practically obliterated.

A condition not entirely unlike this has developed recently in some of the large cities of this country as the result of the present well-meant efforts to save the lives of foundlings. As is well known the death rate among foundlings kept in large institutions is very high. When in addition to the risks of institution life there is artificial feeding, very few of the children survive infancy. In some places the state of affairs which developed was so dreadful that it well deserved the name invented for it by a caustic German physician, "Engelmacherei" (angel-making). In recent years, as the result of farming out infants to wet nurses the death rate among foundlings has been very materially decreased. As a matter of fact, according to some recent statistics there would seem to be less mortality among foundling children thus farmed out, than among the general run of the infantile population. We fear, however, that in this matter at least there has been some juggling with statistics, and that the figures given are those prepared for the purpose of producing an impression upon boards of charities, or legislative committees.

Now comes the interesting contrecoup to the decrease in foundling mortality. Those who are most closely in touch with the poorer classes of the population, mainly Italians, Bohemians and certain Russians and Germans, who now accept the care and wet-nursing of infants for a consideration, have been led to the impression that at times not sufficient care is taken of the children of the family itself, there being a definite knowledge that in case of the death of their own infant, the mother will be able to add quite an important increment to the monthly wage of the family by acting as a wet nurse for a foundling. This seems an entirely inadequate motive to suggest for a maternal neglect of her own child, especially by a woman only recently become a mother and as yet nursing. This is, however, just exactly the state of affairs that was found to exist in England as regards infantile insurance in cases where there was even less money involved. When infants are sickly and require a great deal of care, it is rather easy for a mother to neglect them sufficiently for death to take place, yet without absolutely resolving that she will shorten the life of her child. When then there is the additional motive that she will have another infant to care

for and be well paid for it, neglect may very readily take place.

It seems sure that the mortality among foundlings adopted by poor families is less than that among their own children. This, however, has been claimed to be due to the fact that when foundlings are placed in a family the family is in many cases visited regularly by a trained nurse who suggests to the foster mother the various precautions necessary to preserve the health of the child, or the infants must be brought for regular examinations when suggestions are made. It is understood, too, that in case the foundling does not do well in the family it will be taken away. This regulation especially is said to act as a wonderful help in securing the exercise of due care for the child. It seems unfortunate that some of this helpfulness of modern science cannot be exerted for all infants as well as the foundlings, but thus far it has been difficult to secure proper attention to advice with regard to such matters.

It would seem that some of this experience with regard to the foundlings and their presence in families may of itself have a highly educative value in bringing up mothers to the proper recognition of up-to-date methods in the care of their own children that will eventually compensate for the increased mortality now apparently due to the prospect of having a foundling to care for and being paid for it.

This is the most hopeful feature of the present outlook. The system established by the former Commissioner of Charities in New York City for the care of our foundlings has undoubtedly done very great good and saved many infantile lives. The problems in sociology, however, which it has brought up are deserving of careful study and will prove a fruitful source of material for the development of significant ideas with regard to the improvement of the condition of the poor.

SURGICAL TREATMENT OF PYLORIC CARCINOMA.

Although it is now twenty-five years since Rydygier, with marvelously bold stroke, first removed the stomach for malignant disease, and despite the fact that hundreds of variously designed resections have since been successfully accomplished, the fact remains that the percentage of deaths from gastric neoplasm is steadily increasing.

The efforts of the surgeon have in no way kept pace with the dread and unknown increment factor of this disease. This has led to continued effort on the part of abdominal surgeons to devise a means of meeting this increment by operative procedures less fatal and more effective than the early technics.

In the March number of the *Annals of Surgery* W. J. Mayo outlines a technic which, in his skilled hands, has yielded such admirable results as to justify the belief that a welcome light has been cast on this dark and difficult problem.

Mayo is convincingly explicit. He declares that temporizing with laboratory methods is a futile and dangerous waste of time; early exploratory incision being positively the only method suited to surgical diagnosis. He emphasizes his already reiterated belief that many gastric carcinomata spring from the bed of ill-healed ulcers. Best of all he negatives the dictum that was taught and believed for many years that the presence of a tumor of itself demonstrated inoperability. This, he holds, is by no means true. A small movable tumor in the pyloric region may be a favorable indication, it having been observed that patients with marked symptoms of gastric carcinoma but without any evidence of pyloric obstruction, prove on exploration to be the victims of advanced and hopeless disease. Early pyloric stenosis must, therefore, from now on, be regarded as a benignantly favorable expression of the malignant growth.

Eight months ago the author presented the technic of a composite operation which removed all save the dome of the stomach. Subsequent operations, in which he found the element of shock to be of considerable importance, led him to modify the technic until he now considers that he has found the desired medium between a minimum of shock and a maximum removal of the organ. This technic has been employed thirteen times with but one death.

Although the ultimate results of the operation are less encouraging by far than in those for the relief of mammary carcinoma, the condition is by no means hopeless. Kocher reports that no less than six of his cases have been well three years after operation, one after eight and the other after thirteen years being in the best of health. There is then, very emphatically, a *raison d'être* for trying.

The modification of Mayo's more radical operation seems to offer so much hope in a hitherto nearly hopeless condition that the technic cannot be too broadly circulated. It is only by continual iteration that the mass of the profession can be brought to a realization, at the present stage, at

least, that hunting for HCl and peering into foul-smelling pools of stomach contents for the elusive Boas bacillus, or cotton-bale yeast is nothing more or less than a gentlemanly way of putting a quietus on the unfortunate patient. Let the surgeon explore.

It is not the part of radical surgery but of the most conservative, modern medicine to make this appeal. Mayo complains that it is *not* the patient or his friends who turn aside the exploring knife but, in almost every case, the attending physician!

FACIAL NEURALGIA.

Probably no class of cases is more pitiable than those of the patients who come complaining of severe paroxysmal facial neuralgia, for which ordinary drugs give no relief. In the last twenty-five years at least a dozen different operations, each one of them more severe and more dangerous and presumably more radical than its predecessor, have been devised for the purpose of curing such neuralgias. All the various nerves of the face have been divided farther back at each successive operation until finally even the skull has been opened and the Gasserian ganglion removed. Needless to say this is an extremely dangerous operation. Even in the hands of experienced surgeons many patients have perished from it.

Very few physicians in practice in our large cities have failed to see some of these cases in which a number of operations have been done, each one affording relief for some time, but always followed by recurrence of the painful attacks. Even the removal of the Gasserian ganglion has not proved absolutely curative in a certain number of cases, and patients with marks of having had a large osteoplastic resection of the skull performed are still going to clinics complaining of their awful attacks of pain in the face. Usually they become the victims of the morphine habit, but even morphine fails to give relief after a time, and the coal-tar products are abused to an awful extent by them. Some few of these cases have yielded very surprisingly to quinine. Whenever there is a regular interval between the attacks of pain no physician or surgeon should think of recommending an operation until quinine has been tried. Even when the paroxysms come irregularly, if there is a history of the patient's having had malaria, quinine must be tried over long periods.

These cases constitute one of the most serious opprobria of modern medicine and surgery. It is extremely interesting, therefore, to find a new possible explanation of the origin of the pain and relief afforded by another form of treatment, which by no means involves very serious operation. At the last meeting of the Medical Society of the State of New York, Dr. Sargent F. Snow, of Syracuse, reported a series of cases of tic douloureux and other facial neuralgias which had been cured by treatment of the intranasal structures and of the accessory sinuses of the nose. In the discussion, Dr. Roe, of Rochester, said that his own experience confirmed that of Dr. Snow, and he felt sure that in most cases relief would be afforded by proper intranasal and auxiliary treatment. As in some of these cases serious operations upon nerves had already been performed with only passing success, these suggestions deserve the attention of all those who have these unfortunate patients come under their observation.

It is not difficult to understand that pressure within the nose itself and within the accessory sinuses may very well set up a very obstinately intractable form of paroxysmal pain. Extremely delicate nerve endings are pressed upon by fluid collections under pressure, and the result is sure to be painful nerve explosions. Whether these pathological conditions associated with the nose and its sinuses will explain all of the cases of tic douloureux remains to be seen. They certainly do include, however, a good many cases formerly thought to be facial neuritis of some form, and the apparently more enduring relief that can be afforded under the new and more correct diagnosis is of itself sufficient to make this a noteworthy advance in medicine, if further experience will confirm the observations so far reported.

ECHOES AND NEWS.

NEW YORK.

Examinations at Brooklyn Hospital.—At the examination held at Brooklyn Hospital for the appointment of four new internes, the following men from the College of Physicians and Surgeons were successful: First place, W. H. Lohman; second, J. T. Rose; alternate, F. H. Wilson. The third place was taken by a Syracuse student, and the fourth by a Bellevue man.

Dates for Hospital Examinations.—A partial list of the hospitals in this city which will examine applicants for interneships during March and April, are appended: German Hospital, March 21; Bellevue, March 24, 25, 26; Mount Sinai, March 24, 25; Methodist Episcopal of Brooklyn, March 26; Post-Graduate, March 28 and 29; the German Hospital and Dispensary, March 31; S. R. Smith Infirmary, April 1; Lying-in, April 4; St. Luke's and Presby-

terian, April 4 and 5; City, April 5; Roosevelt and New York, April 11; St. Joseph's, April 12; Ruptured and Crippled, April 13; General Memorial, April 14; Gouverneur, April 18 and 19; St. Francis', April 19; Lincoln, April 19 and 20.

Proposed Change in License of Dogs and Cats.—Assemblyman Ellis, on March 15, introduced in behalf of the New York City administration a bill transferring from the Society for the Prevention of Cruelty to Animals to the City Health Department all jurisdiction over the licensing of cats and dogs in the City of New York. The bill was prepared under the direction of Dr. Darlington. It is to be supported by arguments citing the growing belief that the suppression of the vagrant dog and cat nuisance in cities is a matter more vital to the health of the people than it is from the viewpoint of cruelty to the animals, and that contagious diseases are believed to be carried from house to house by cats.

Plan to Combine Dispensaries.—An adjourned meeting of the Board of Surgeons of the New York Eye and Ear Infirmary was held last Saturday at the Infirmary, corner of Second Avenue and Thirteenth Street, when the committee of three, composed of Drs. P. A. Callan, D. W. Hunter, and W. E. Lambert, appointed at last Thursday's meeting to inspect the Gouverneur Hospital reported to the Board of Surgeons. The committee spent Friday afternoon going over the trachoma pavilion, or contagious diseases of the eye wing, of the Gouverneur Hospital, with a view of determining whether it will be possible for the city's cases to be taken over by the New York Eye and Ear Infirmary. Through Dr. Brannan, representing Dr. Darlington, the Health Commissioner, overtures were made to the Board of Directors of the New York Eye and Ear Infirmary, with a view to closing the trachoma ward at Gouverneur Hospital, and sending the city's cases to the infirmary, to be treated in the Platt pavilion, which was closed on March 1 last. If the work can be done by the Infirmary for $15,000 or $18,000, it is possible, according to a statement by the Board of Surgeons, for the work to be done at the infirmary. If the city can agree to pay a reasonable sum for the work, annually, the closed Platt pavilion, which is operated only under heavy expense, will be reopened at once to meet the demand for treatment of the school children suffering from trachoma. A woman, who desired her name withheld, has sent a check for $500 to John L. Riker, treasurer of the Infirmary, with her best wishes for the success of the work.

Manhattan Dermatological Society.—This society held its regular meeting on March 4, 1904, at the residence of Dr. Weiss; Dr. Oberndorfer, presiding. Dr. Gottheil presented case of gumma of conjunctiva of right lower eyelid. Diagnosis accepted universally. He also presented a case of epithelioma of tongue in male, six to seven years' duration, excision of nodule on tip of tongue years ago; recurrence on right side posteriorly; ulcer with hardened base. Dr. Weiss advises removal of jagged teeth in conjunction with ordinary treatment.

Dr. Oberndorfer presented boy with pemphigoid eruption on face. Patient when presented to this Society before had well-marked bullous lesions; now only more or less diffused erythematous spots to be seen.

In the absence of Dr. Ochs Dr. Gottheil presented a woman with maculosquamous syphilide on upper lip, chin and margin of hair and forehead. Child of woman, six years of age, has a very similar lesion on the right side of upper lip; child well-nourished and no other symptoms. Unanimous agreement that mother's lesion is syphilitic; Dr. Gottheil considers child's lesion syphilitic also. Dr. Moses had made histological examination of scales on child's face for the purpose of excluding trichophyton; no fungus found. Dr. Weiss considers lesion in child a simple non-syphilitic eruption; Drs. Cocks and Oberndorfer agree in the main with Dr. Weiss.

Dr. Gottheil presented a child, two months old, with syphilis congenita and eczema intertrigo, of seven weeks' duration; Drs. Oberndorfer and Moses agree to diagnosis made; Dr. Pisko considers lesion psoriasis; Dr. Weiss excludes syphilis at first but subsequently alters his opinion so as to consider syphilis a possibility.

Case presented by Dr. Gottheil for Dr. Ochs. Woman with macular eruption on chest and sides, which at one time looked very much like a pityriasis rosea. Has had eruption off and on for two years, and syphilis has at various times been thought of. Dr. Weiss, after taking into consideration the generalization, scaliness, long duration and absence of concomitant luetic symptoms, diagnoses seborrheic eczema; others present concur.

Dr. Gottheil presented a woman, who had already been presented as case of lichen planus corneus. Papules now principally on wrist. He also presented a case of bromoderma. Pustular, acne-form leg and thigh lesions.

Dr. Pisko presented a woman with a characteristic case of lupus erythematosus. Left side of face had been swabbed with formalin, causing severe pain and a new crop of lesions; one application of trichloracetic acid with good result on right side; must be applied gently.

Dr. Weiss presented a woman with lupus erythematosus; Dr. Cocks thinks morphea exists on right side of face also.

Dr. Gottheil reports four cases treated with Finsen ray and three cases cured and not yet relapsed. Some cases look at times like seborrhea, at other times they look like lupus erythematosus. Dr. Moses found the Finsen light useful or curative in a large number of cases at the Finsen Institute. In one very severe case in a man, he observed an almost perfect result from painting the lesions with tr. iodi and the use of quinine internally; Dr. Weiss agrees generally with suggestions made.

Dr. Pisko showed a typical case of psoriasis; well-marked and with typical course.

Dr. Weiss presented a case in a middle-aged woman; the lesions consist of small, red papules on axillary folds and on abdomen and which he designates provisionally as lichen ruber acubus. Dr. Cocks considers that it could be grouped among the eczemas, but Drs. Pisko, Gottheil and Jacobson agree in the main with Weiss, although claiming it as a lichen simplex and advise further study, both histologically and clinically before definitely classifying it under a special rubric. Dr. Moses proposes to excise one of the lesions for histological examination.

Dr. Moses presented a case of multiple syphilitic infection in a young married man. Patient presents a typical indurated urethral chancre one-fourth inch posterior to meatus; also an indurated subcutaneous nodule in scrotum, immovable and firmly attached to epidermis. The latter has been extirpated for histological examination, and in healing the operation wound has reindurated. The scant secretion from urethra on microscopical examina-

tion shows the absence of pus cells and gonococci; numerous bacteria and cocci are present. The histological examination of scrotal lesion has not been completed; also two lesions on corona glandis. Two crusted ulcerations exist on right forearm, which simulate both a serpiginous syphilide and a simple impetiginous eruption. Dr. Gottheil diagnoses multiple syphilitic infection; possibly a quadruple infection. Dr. Cocks considers the lesions on arm gummatous, and those on corona glandis serpiginous syphilides; in regard to lesion in meatus he requires further observation before making diagnosis. Dr. Weiss considers lesion on meatus as undoubtedly an initial sclerosis, although the absence of glandular involvement is remarkable.

Dr. Oberndorfer presents a man with lichen planus. The patient is also afflicted with an artificial dermatitis which he considers as due to having worn an undershirt from a deceased friend, and presents many new scratch lesions; the latter lesions are of three weeks' duration.

PHILADELPHIA.

Leper to Be Returned to Hawaii.—An Hawaiian leper has been discovered in this city after living here for three weeks. He sought treatment for blotches on his skin, this leading to the diagnosis of leprosy. It is said that the man will be returned to join the leper colony in Hawaii.

Smoke Ordinance Adopted.—City Councils have passed a smoke ordinance, to go into effect next October. The bill does not include all that its promoters desired, but it is at least a beginning toward a less vitiated atmosphere. The standard fixed by councils is the regulation color scale of two densities and the limitations of the various smoke-producing establishments have been specified. A fine of $25 is to be paid for each failure to comply with the requirements.

Epidemic of Measles.—There are more than 3,000 cases of measles now under treatment in Philadelphia, and during the past week 17 children died from the disease. Physicians say they have found more serious results from measles during the past winter than are usually met with in cases of scarlet fever. This is considered largely due to the fact that greater precautions are usually observed in connection with the latter disease, measles being looked upon as an exceedingly mild and comparatively inoffensive infection. With the present epidemic this is not true and parents are being advised to call a physician at once when the attack begins.

Philadelphia Hospital Residents.—Considerable apprehension is being felt by the students of certain of the medical colleges of the city regarding this year's Philadelphia hospital appointments which are looked upon as among the most valuable hospital positions open to Philadelphia graduates. This feeling is due to the fact that equal representation among the three larger colleges, with a certain number of representatives from the Woman's Medical College, is to be abolished and the appointment made according to standing in an examination soon to be held. This sounds fair enough and a strictly impartial examination is promised by those in authority; nevertheless there is a quite general opinion that politics will sooner or later again have much to do with the appointment of internes.

High Death-rate Since January 1.—From January 1 to March 19 this year the deaths from all causes have been 7,983, this being 1,761 more than during the corresponding period of 1903. Deaths from pneumonia lead the list with 1,227, the second being tuberculosis with 704 deaths. Measles has helped swell the rate by furnishing 93 of the fatal cases, as against 25 during the first three months of 1903.

Dr. Maragliano Ill.—Owing to the illness of Dr. Edoardo Maragliano, of Genoa, Italy, he will be unable to deliver his address on Tuberculosis, under the auspices of the Phipps Institute, which was scheduled for March 28. Dr. Maragliano has, however, authorized Dr. Lawrence F. Flick to read his address on that evening.

CHICAGO.

Talks on Nervousness.—During the coming summer an interesting course of lectures for teachers and graduate nurses will be given under the auspices of the Chicago Hospital School for nervous and delicate children. The lectures will cover the field of work with defective and abornmal children. Among the physicians who will lecture are Dr. Daniel R. Brower, Dr. Archibald Church, Dr. Henry B. Favill, Dr. Hugh T. Patrick, Dr. Eugene S. Talbot, Dr. H. V. Halbert, Dr. N. B. Delameter, Dr. Harold N. Moyer, Dr. Truman W. Brophy, Dr. Frank Billings, Dr. W. S. Christopher, Dr. Frank Allport, Dr. Julia Holmes Smith. A number of specialists from other cities will also present interesting phases of the work. The complete program will probably be in readiness about the middle of April. During the last two years the school has had a large correspondence class of teachers, and it is the aim of the institution to make it possible for these outside teachers to come together for the discussion of their problems and to have presented to them from the physician's point of view the most scientific methods of handling such children. The course is open to parents as well as teachers.

Iroquois Hospital Plan.—The proposal of the Iroquois Memorial Association to establish an emergency hospital in the business district in memory of the victims of the theatre fire has been indorsed by the Chicago Medical Society. The action of the society was embodied in a resolution presented by Dr. Andrew M. Harvey and seconded by Dr. W. A. Evans. The preamble lays stress on the need of a hospital in the heart of the city and the resolutions continue: "Resolved, That the Chicago Medical Society approves the action of the trustees of the Iroquois Memorial Emergency Hospital in their generous effort to give to the people of Chicago a modern, fully equipped and endowed hospital capable of rendering prompt assistance to those cases of unexpected injury and sickness, which are of daily occurrence, and be it further resolved, that we, as a society, tender to the hospital our counsel, advice, and professional service whenever required."

Another National Anti-tuberculosis Association.—To prevent tuberculosis by legislation and through a campaign of education is the object of an organization incorporated in Springfield recently under the name of the National Anti-Tuberculosis Association. The incorporators are Dr. W. B. Metcalfe, Rev. F. M. Carson, C. W. Hanford, Alderman W. M. Butterworth and Walter R. McDonough, all of Chicago. According to the incorporators the association is purely philanthropic. They expect to enlighten the public through lectures and publications and to urge several important legislative measures that will check a spread of the disease. There is not a tuberculosis clinic in Chicago, and they mean to establish one in the downtown district as soon as possible. Several doctors are interested in the association and the list of directors will show a large number of the prominent business men of the city. A campaign of education and for better legislation is needed to protect families. In the way of legislation the most

apparent need is a registration of patients suffering from tuberculosis. In the Eastern States there is such a registration and it has done great good. A hospital for the treatment of the disease may be established later.

Order of St. Joseph to Erect Hospital.—Plans for the Hotel Dieu, a religious hospital to be built for the Hospitalers of St. Joseph, who came here from Kingston, Ont., have been prepared by Architect George A. Beaudry. The building will be erected at the corner of Harvard avenue and Sixty-fourth street, and will be four stories high, covering an area of 165 by 175 feet, and be of fireproof construction. The exterior will be of Bedford stone, with tiled mansard roof, above which will rise an ornate dome 68 feet high. In the halls there will be enameled brick wainscoting with marble and mosaic work, and the building will embody all the improvements that go to make up a first-class hospital. The cost is estimated at about $200,000. This, however, will be but a part of the building, which, when complete, will have a frontage of 225 feet and a depth of 175 feet. Rev. Bernard P. Murray, pastor of the St. Bernard's parish, will have charge of the building.

Consumption and Pneumonia.—The Chicago *Tribune* under date of March 12 has the following to say with reference to these two diseases: "In the United States in 1899, 105,971 people died of pneumonia as against 109,750 who died of tuberculosis of the lungs. As comparative numbers they stood appallingly close together. But even in the matter of human life there may be economic differentiation. Economically it is a fact of tremendous significance that 33,807 of the victims of pneumonia were under two years old. Human lives, it is true; infants which might have had vital bearing upon the future of society and State. Yet from the economist's point they were physical weaklings upon which little had been spent. But what of tuberculosis? It is of inconsiderable peril until the age of ten years. Between the ages of fifteen and nineteen years, however, its black shadow has eclipsed that of pneumonia, and between the ages of twenty and twenty-four years it has reached its maximum in 16,031 deaths in one year. Human lives? Yes, lives that are just equipped for the beginning of life and living—lives upon which the maximum has been spent in preparing for life. For 1899 the census showed 24,905 deaths between five and forty-five years from pneumonia as against the 72,960 from tuberculosis. At the flood tide of life phthisis takes three times as many people as pneumonia. But of the 24,905 victims of pneumonia there are other facts of vital bearing. Broadly speaking, the victim of pneumonia is a weakling. The reports of the census show that from fifty-five to seventy years there is an increase in deaths from pneumonia with a more than corresponding decrease from tuberculosis."

Inspection of School Children.—The Board of Education of Chicago through Dr. Henry Hartung has formulated the following routine for the examination of school children: *Eyes.*—Diseases of the conjunctiva and lacrimal apparatus, muscles of the eyeball, visual acuity, hypermetropia, myopia, astigmatism. *Ears.*—External ear, auditory meatus, drum membrane, hearing, acute or chronic diseases of middle ear. *Mouth and Pharynx.*—Defects of tongue, lips, palate, condition of teeth, hypertrophy of tonsils, pharyngitis, adenoids, granulations, etc. *Nose.*—Acute or chronic rhinitis, nasal hypertrophies, polypus, deflection of septum, etc. *Chest.*—Abnormal development, round shoulders, spinal deflection, diseases of the heart and lungs. *Skin.*—Acute or chronic affections, scabies, pediculosis, favus, etc. *General Nutritional and Structural Disorders.*—Anemia, chronic headaches, glandular enlargement, tuberculosis, deficiency of muscular development, nervousness, chorea, or any pathological condition which may retard the pupil's growth or influence his progress in school work.

Treatment of Bronchitis, Bronchopneumonia and Pneumonia in Children.—In a paper on this subject, read before the March meeting of the Chicago Pediatric Society, Dr. James Warren Van Derslice stated that in many children there was a tendency toward catarrhal inflammations of the air passages. How to remove this tendency was a hard problem. No amount of cod-liver oil and tonics would overcome this predisposition without good hygiene. The temperature of the rooms was kept too high; the temperature of living rooms should be 68° to 70° F. Children should be accustomed to outdoor air. This should be begun in the summer and continued throughout the year except in case of a storm, when the child should be dressed for outdoors and taken in a room, with windows wide open, for twenty minutes to half an hour. Cold sponge bath of the chest and arms every morning was of value. The child's underclothing should be of wool, the lightest weight in summer, and only medium in winter. Chest protectors should be discountenanced. Care must be taken that the feet are kept warm and dry. The mistake in dressing the child was almost always on the side of too much rather than too little clothing. The sleeping room should always be supplied with fresh air, and the child should sleep in flannel night-clothes. The sending of patients to a warmer climate during the winter season was necessary in a few cases, but he believed the majority of them did better in a dry cold climate. He discussed the general management of these cases, and then spoke of the value of inhalations of steam, saying they were not sufficiently appreciated. These were best given in a tent by placing medication in a quantity of boiling water, as the use of lamps in a tent deoxidized the air too much. Three quarts of boiling water in an earthen vessel would produce steam for ten minutes, which was about the length of time these inhalations were usually given. They should be given every two to four hours. Simple lime water inhalations were the best; later creosote, pine needle oil, compound tincture benzoin, terebene, turpentine, camphor, oil of eucalyptus, or eucalyptol might be used. Internal medication should be entirely symptomatic. The indications for treatment, in the main, were nutritional, stimulant and hygienic.

Thoracic Difficulties of Childhood Exclusive of Cardiac; Differential Diagnosis.—Dr. S. V. Balderston urged a closer study of the physical signs in thoracic disease of children. Auscultation alone is not sufficient. Pile-driver percussion is not suited to the child's chest. In these conditions, dyspnea, cough, cyanosis and nervous manifestations may be called cardinal symptoms. One should study the conditions within the air pasages and cavities which prevent free admission of air or cause irritation; also the conditions in the lungs and chest walls. Finally, the reflex and central conditions should be carefully studied. He divided the subject into two groups: (*a*) acute, and (*b*) chronic. Croup was used as a comprehensive term to include a variety of conditions in which there is a tendency to spasm of the glottis. Enlarged tonsils and adenoids are usually present; as an inciting cause catarrhal spasm of the larynx may be confused with acute bronchopneumonia at the outset. History of afternoon hoarseness, amenability to antispasmodics, and return of attack the following night indicate catarrhal spasm. Laryngismus stridulus is excluded in which there are periods of complete cessation of respiration. Acute bronchitis. (*a*) Simple; (*b*) severe, and (*c*) capillary bronchitis. (*a*) In mild cases the question is whether it is merely a

complication of another disease. (*b*) Onset of severe bronchitis cannot be differentiated from pneumonia. Exaggerated, not bronchial, breathing observed all over the chest. Any impairment of resonance or suggestion of bronchial breathing excludes bronchitis. (*c*) Capillary bronchitis, no attempt is made to differentiate it from bronchopneumonia. Pneumonia. Bronchopneumonia signifies a low resisting power. It presents the symptoms of a mixed infection. At the onset there was marked prostration and cyanosis; variable temperature, very high or very low. There are indefinite areas of consolidation and bronchial breathing, marked dyspnea, great mortality. In lobar pneumonia the physical signs are all-important; there is the most difficulty in central consolidation. The physician should watch for bronchial fremitus. The characteristic signs were defined area of dulness and bronchial breathing. Chronic conditions. Here it is a question as to whether or not there is infection by the tubercle bacillus. In cases of chronic cough and chronic pneumonia following pertussis and measles, *Bacillus tuberculosis,* enlarged tonsils and adenoids may serve to keep up the cough. Enlargement of the bronchial glands irritates the recurrent laryngeal. This enlargement may be tuberculous or not. In children tuberculous infection of the lungs probably starts from the center through infection from these glands; hence there is rarely infection of the extremes of the lung. Cavernous breathing and cracked-pot sounds do not indicate cavity, but consolidation about a bronchus. The family history should be carefully investigated, likewise the surroundings, also for foci in other parts of the body.

GENERAL.

State Manufacture of Antitoxin in New Jersey.—Dr. F. C. Henry, a practising physician in New Jersey, has introduced a bill in the legislature of that State recommending the building of a plant for the wholesale manufacture of diphtheria antitoxin. Dr. Henry's bill provides as follows: "1. The State Board of Health shall provide such laboratory or laboratories, apparatus, materials, and other requirements necessary to make or prepare and distribute diphtheria antitoxin to the inhabitants of the State. 2. The State Board of Health shall make or prepare and distribute without charge, in sufficient quantities to supply the inhabitants of this State, diphtheria antitoxin in such manner through local boards of health, or otherwise, as the said State Board of Health shall by rules determine. 3. This act shall take effect immediately."

The bill is endorsed by the State Board of Health, which has plenty of facilities for making antitoxin. The measure was referred to the Judiciary Committee and it will probably soon be reported and rushed through.

Massachusetts is said to be the only State of the Union which at present owns and controls its antitoxin laboratories.

Canal Site a Pest Hole.—In a report to the Government upon sanitary conditions in Panama, Dr. Claude C. Pierce, assistant surgeon in the service, says that the climate there is likely to prove a menace to all American visitors for some time to come. No isolation of infectious diseases is compulsory, and their prevalence in that region is well known to everyone. Leprosy is more or less common in Panama city, along the Panama railroad, and in the country districts. Beriberi has been common since 1897, and there are now thirty cases in the French hospital in the above-named city. At present there are very few cases of smallpox, because provision has been made for a general free vaccination. The other diseases commonly seen are tuberculosis, dysentery, elephantiasis, yellow fever and estivo-autumnal malaria. Dr. Pierce says that the climate at the isthmus "practically prohibits efficient work, and would lead to a wanton sacrifice of human life impossible to estimate were American laborers sent there in large numbers."

Physicians in Demand.—The German and Russian governments have prevented the holding of the Tenth Congress of Polish Physicians and Scientists, which was set to be held at Lemberg, Austria, July 2 to 24, 1904, as their presence is desired at home.

Meningitis in Malone.—This town has been suffering from an epidemic of cerebrospinal meningitis the past two weeks, and eight deaths have resulted. As the disease has been confined solely to school children, the Board of Education, at a meeting this week, voted to close the schools until such time as the epidemic is checked.

Hospitals under Construction.—According to *Charities,* nearly a million and a half dollars is now being spent, or is about to be spent, in some nine different States for new buildings for the insane. This is exclusive of New York State, where between $600,000 and $900,000 is annually expended for this purpose. It would seem pertinent to inquire whether there might not be an increase in efficiency and decrease in cost if the experience of the different States were in some way made available to one another. We have practically the same classes of patients to be provided for in all cases, and there is little reason why buildings which have been found suitable in Massachusetts should not be suitable in Oregon. The building operations now under way, or already planned, include entirely new institutions at Norwich, Conn., Allentown, Pa., and Parsons, Kansas, and additions to existing buildings at Norristown and Harrisburg, Pa., Spring Grove and Sykesburg, Md., Dunning and Watertown, Ill., Lyons View, Tenn., Hopkinsville, Ky., San José, Cal., Eloise, Mich., Las Vegas, New Mexico, Norfolk, Neb., and Pineville, La. The buildings include administration buildings, nurses' homes, cottages for convalescents and buildings for almost all other classes of patients. These buildings are probably designed in most cases by architects who have little familiarity with the requirements of the insane or with expert opinion on the subject of their accommodation. It is not customary for architects to specialize on institution construction, and the appointment of an official State architect has probably never been considered in most cases. Problems which have been solved only after many failures in some of the older States are, perhaps, worked out afresh without adequate data. In 1891, William P. Letchworth, a member of the New York State Board of Charities, wrote a valuable paper on "Poor-house Construction," which was transmitted by the State Board of Charities of the legislature and was afterward reprinted and circulated for the information of the public. How helpful it would be if some expert in hospital construction would prepare a treatise on the construction of institutions for the insane, illustrated with plans and elevations and equipped with references to localities where successful exponents of sound theories of construction could be seen and studied.

London Medical School Endowed.—Sir Donald Currie has given $500,000 to the University College and London University. It is intended with this sum to build a school of advanced medicine, and it will also enable the university to incorporate the college in its system.

X-ray Anniversary.—It is announced that in 1905, the tenth anniversary of Roentgen's famous discovery of the X-rays, a Roentgen celebration will be

held in Berlin. This will include an exhibition of Roentgen apparatus, and persons desiring information regarding the arrangements should communicate either with Prof. R. Eberlein or Dr. Immelmann, of Berlin.

Iowa Hospital for Drunkards.—The Iowa State Senate on March 18 voted an appropriation of $125,000 for the location at Knoxville of a hospital for habitual drunkards. This is the first open approval of Iowa's so-called "dipsomaniac law." This law, which went into effect two years ago, has been severely criticized.

The Plague at Pretoria.—The bubonic plague has appeared here, but is well in hand and is confined to the coolie population. There has been one death.

OBITUARY.

Dr. Thomas McInnes, Senator from British Columbia, and subsequently Lieutenant-Governor, died at Vancouver last week. He was a pioneer in British Columbia.

Dr. James Brownlee Sanford, Speaker of the Colorado House of Representatives, died at Denver last week of appendicitis, aged thirty-five years. He was born at Penn Yan, N. Y.

Dr. Moreau Morris died last week at his home in East Seventeenth street, this city. He was born at Stillwater on June 19, 1825, and was graduated in 1848 from the College of Physicians and Surgeons. In 1866 he was appointed health commissioner, and from 1870 to 1872 served as superintendent of the New York City Health Department and State cattle commissioner. In 1871 he became surgeon of the Seventh Regiment, N. G., S. N. Y., and served until 1884. Immediately following his retirement from the National Guard he was appointed tenement house commissioner. Dr. Morris was a member of the Seventh Regiment Veteran Association, of the American Public Health Association, of the Alumni of the College of Physicians and Surgeons, and of the Academy of Medicine.

Dr. William Frederick Holcombe, for many years one of the most distinguished physicians in New York and a noted specialist on diseases of the eye and ear, died suddenly last week in the Presbyterian Hospital, after a brief illness, from a general breakdown due to old age. Dr. Holcombe lived for years at No. 54 East Twenty-fifth street, and treated General Grant during his last illness. He also treated Daniel Webster and Charles Sumner. Some ten years ago he became deaf, and through this affliction was compelled to give up his practice, as well as his professorship on diseases of the eye and ear in the New York University Medical College, the New York Ophthalmic College and Hospital, and the New York Medical College for Women. He was born in Stirling, Mass., April 2, 1827. Dr. Holcombe was one of the founders of the New York Genealogical and Biographical Society and was a member of the International Medical Association.

Dr. Frank K. Irving, electrotherapeutist of the City Hospital at Newark, N. J., died in that institution last week of tuberculosis to which he subjected himself in his search for a means of curing that disease by reaching the germs with the electric current and forcing a mineral solution through the tissues to the affected parts. Dr. Irving was thirty-five years old and was born in Fort Wayne, Ind.

Dr. Thomas W. Watkins died last week at his home, 453 Forty-second street, Brooklyn, in his seventy-sixth year. He was a son of the late Dr. John Watkins of London, England, who was among the first to use chloroform in medical practice. The son came to this country thirty-five years ago and settled in Brooklyn.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, March 3.

ROYAL VISIT TO CAMBRIDGE—INDISPOSITION OF THE KING—HEALTH OF THE BRITISH NAVY—LORD NELSON'S LOST ARM—PREJUDICE AGAINST LADY DOCTORS.

On March 1 the King and Queen visited the University of Cambridge for the purpose of formally opening the new museums and laboratories now approaching completion. It is fifty-six years since a reigning sovereign has shed the light of his material countenance on the ancient seat of learning that lies among the sedges of the Cam, and the visit was made the occasion of a display of exuberant loyalty which among the undergraduates took the form of rowdiness and "ragging." The King wore the scarlet robes and quaint hat of a Doctor of Laws. It may be mentioned by the way that His Majesty's academic millinery is almost as varied as that of his Imperial nephew of Germany is in the way of military uniforms. King Edward, besides his Cambridge doctorate, is a D.C.L. of Oxford, a LL.D. of the Universities of Glasgow, Dublin, Calcutta and Wales, and a Doctor of Music of the Royal University in Ireland. It may be added that he is an Honorary Fellow of the Royal Colleges of Physicians and Surgeons, having in each of these capacities the privilege of wearing special raiment of a more or less decorative character. He was himself a student, both at Oxford and at Cambridge and to Trinity College in the latter University he sent his eldest son, the late Duke of Clarence. In the Senate House the King made a little speech which—it may be mentioned for the information of a certain New York specialist who made a confident diagnosis of laryngeal cancer on no better foundation than the huskiness of the royal voice—was delivered in clear, strong tones. One passage was specially significant. He declared that he earnestly desired the extension and development of all branches of study and research, and he foretold that Cambridge would continue to occupy a foremost place in this great work. He spoke, too, of the new endowments of education which were necessary if it was to be kept up to its proper standard of efficiency. It is to be hoped that this hint from the King will bear fruit, for it is difficult to get the British public to see that such endowments are required. Their view of education is that expressed of literature by William Pitt. When that statesman was asked to grant a pension to a meritorious man of letters, his reply was "Oh, literature can take care of itself!" The new buildings of the Cambridge Medical School will add considerably to its efficiency. It is already the largest school of medicine in England, but the teaching has hitherto been crippled by the want of laboratories and equipment.

The day of the royal visit to Cambridge was bitterly cold and it was noticed by some of those present at his reception that the King's face was almost cyanotic and his breath very short. He has to a large extent regained the Falstaffian girth which he partly lost after the operation. He has greatly aged within the last year or two, and his general appearance is that of a man whose constitution is undermined. To-day it is announced that he caught cold at Cambridge, but the indisposition is said to be slight. There can be little doubt, however, that from an insurance point of view he is a "bad life."

The Statistical Report of the Health of the Navy for the year 1902, which has just been issued, shows that with a personnel increase by 1190 as compared with the previous year, there has been an increase of

cases of sickness and deaths; on the other hand there has been a decrease of invalidings. The following are the figures:

Year.	Cases.	Deaths.	Invalidings.
1902	85,769	590	2,985
1901	84,026	526	3,108

The total force serving afloat in 1902 was 99,600, so that the aggregate number of cases of disease and injury recorded in the year furnishes a ratio of 861.13 per 1,000, which shows an increase of 7.3 per 1,000, as compared with the ratio for 1901, but a decrease of 22.2 when contrasted with the average of the last five years. The average number of men sick daily was 3,523.39, giving a ratio of 35.37 per 1,000, and showing a decrease of .02 per 1,000 compared with 1901, and of 1.71 in comparison with the last five years' average. The total days' sickness on board ship and in hospital was 1,286,038, which represents an average loss of service from disease and injury of 12.91 days for each person, which is the same as the preceding year, and a decrease of .6 in comparison with the average of the last five years. The total number of persons invalided was 2,985, which is in the ratio of 29.96 per 1,000, and shows a decrease of 1.62 per 1,000 when compared with 1901, and a decrease of 1.21 in comparison with the average of the last five years. Of the above total 2,066 persons were finally invalided from the Service, 200 of these refused surgical operation, giving a ratio of 20.74 per 1,000 for the whole force, or 69.21 per cent. of the number invalided, thus showing a decrease of 1.1 per 1,000 when contrasted with 1901. As regards the death rate, the ratio per 1,000 was 5.92, an increase of 0.58 per 1,000 compared with 1901, and a decrease of 0.29 when contrasted with the last five years' ratio. The highest death rate appears on the Pacific Station, viz., 67.42 per 1,000, due to the unfortunate loss of the Condor. There were no deaths on the Southeast Coast of America Station. Only two wounds in action are recorded, with one death. The prevalence of enteric fever and the mortality from that disease show a slight decrease. One case of plague, with a fatal issue, is reported from the East Indies Station. Cholera shows five cases with four deaths on the China Station. A decline in the ratio of cases of primary syphilis is shown, but there is an increase in regard to constitutional syphilis and also to gonorrhea.

An appendix to the blue-book, containing the report on the health of the Navy, gives a number of extracts from journals of medical officers of the Navy between 1793 and 1856. One of the most interesting of these is from the journal of the surgeon of the Theseus; it is dated "1797, July 24th and 25th," and is to the following effect: "Admiral Nelson. Compound fracture of the right arm by a musket ball passing thro' a little above the elbow an artery divided, the arm was immediately amputated and the following given him ℞ Opii. gr. ij. ft. Pil. statim. s., etc., 26 July. Rested pretty well and quite easy. Tea, soup, and sago. Lemonade and Tamarind Drink. 31 July. One of the ligatures came away; looks well. 1 Aug. Continued getting well very fast, stump looked well, no bad symptom, sore reduced to the size of a shilling." It may be remembered that Nelson received the wound for which his arm was amputated in a naval engagement off Santa Cruz. He bore the operation without flinching, but afterward declared that he had suffered much pain from the coldness of the surgeon's knife. This led him to issue an order that surgeons should always dip their knives in hot water before operating. The surgeon of the Theseus says nothing more about the case. The only further reference to it is found in the *Journal of the Seahorse*, wherein the surgeon, Mr. Thomas Eshelby, writes: "I was appointed from the Theseus, to attend the Admiral to England . . . . one of the ligatures not come away. Twitching Pains at times, particularly by night. I gave the following: ℞ Haust. Salin. c. Tr. Opii. gtt xl. h. s. sumendus et rep pro re nata. Dress'd with Cerat Lap Calamin and dry Lint: he landed at Portsmo. 1st Sept. would not suffer the ligature to be touched." It is remarkable that the journal of Dr. Beatty, surgeon of the Victory, which is preserved in the Public Record Office, contains a list of the wounded at the battle of Trafalgar but is absolutely silent respecting the death of Nelson.

The medical profession in this country can furnish some of the most striking examples of fine old crusted conservatism to be found anywhere. When the proposal to admit women to the medical degrees of the University of London was first discussed, the late Sir William Jenner declared that he would sooner see his only daughter in her coffin than working in the dissecting room. He was the trusted physician of Queen Victoria and apparently believed that, although a woman could rule the State, she was unfit by some mysterious defect of nature to prescribe a dose of gray powder to a sick child. Afterward, when the University opened its doors to the ladies, Dr. Wickham Legg, then on the medical staff of St. Bartholomew's Hospital and author of a huge book on diseases of the liver, shook the dust of the University off his feet by resigning his degree; he has since devoted himself to the study of liturgy, which is presumably undefiled by the intrusion of women. Quite recently there has been an equally ridiculous exhibition of a prejudice which, it might have been thought, now existed only in a fossil state. A lady holding the highest professional qualifications was a short time ago appointed medical officer to the Western Infirmary, Westminster. She entered on her duties and gave great satisfaction to the poor patients among whom she worked. The result seemed fully to justify her appointment which was about to be made permanent, when Dr. Allchin, one of the honorary consulting physicians of the dispensary, sent in his resignation. He has been on the staff of the institution for thirty years and the governors found themselves in the awkward position of having to choose between retaining the support of the consulting physician or dismissing a competent and popular medical officer because the appointment of a woman was an outrage to the professional bigotry of the former. To the shame of the governors be it said they decided to sacrifice the lady. Their decision is the more extraordinary since the services of Dr. Allchin are now little more than nominal. He is a man of impetuous temper, who a few years ago threw up the post of Registrar to the Royal College of Physicians because he could not have his own way in some trumpery matter. For no better reason than to smooth the ruffled plumes of his susceptibility, the poor of Westminster have been deprived of the ministrations of an efficient medical officer. There is special need for a lady practitioner in the district. During the short period she has been in office her consulting rooms have been crowded every evening, and at the dispensary, where the patients are nearly all women and children, she was often preferred by those who could not consult a male doctor. According to her testimony there is a stronger feeling in favor of ladies among the poor than among the upper classes. Dr. A. E. Cope, who is also on the staff of the dispensary, has stated that the great bulk of the work of that institution was done among women and children, and having regard to the clientele there was plenty of room for a lady doctor on the staff. It is but fair to say, however, that such manifestations of obsolete prejudice as that just related are now quite exceptional here.

SPECIAL ARTICLE.

BYWAYS OF MEDICAL LITERATURE.—XX.

WILD ANIMALS AND DISEASE.

There are many who think that the wild animals are practically free from disease. Death is popularly supposed to come to them as the result of accident, or sometimes, but very rarely, as the consequence of old age. Very few people imagine that they are quite as subject to many of the diseases which make life unpleasant for human beings, as man himself. For instance, it is practically impossible to keep monkeys in confinement, unless the greatest care is exercised in preventing them from becoming infected with tuberculosis. At least three times in the last thirty years the monkeys in the zoological garden of Vienna have all died, as the result of tuberculosis. It is not alone in captivity either that animals are thus affected. Monkeys in their native wild woods are frequently found dead, having died from tuberculosis. It is even said that most of the carcasses of lions found in the desert of Sahara, contain evidence that the animal suffered during life from this disease, which is sometimes supposed to be the scourge only of insanitary living in crowded centers.

Those who imagine that animals do not suffer from even the minor affections that afflict human beings should read the article on the wild animal surgeon and his patients in the January number of *McClure's Magazine*. In these experiences of a veterinary surgeon, mainly occupied with the wild animals in the New York Zoological Garden, there are many stories of wild animals suffering from flatfootedness, from corns, from ingrowing toe-nails and from toothache. When animals suffer from toothache the affection is apt to be followed by abscess at the root of the tooth that often gives rise to blood poisoning and proves fatal. The same thing is true with regard to the ingrowing claws or nails, especially of the lions or tigers, which have to be operated upon in order to save the animal's life. Animals bear the suffering incident to these ailments very well until toxic absorption brings on a weakened condition, in which they become restless and uncontrollable. The whole subject is interesting as showing how comparative pathology enables us to explain the pathological conditions of the animals on exactly the same principles which form the basis of diseased conditions in human beings.

ANTIFAT CERTIFICATES.

In a story by the English humorist, Jerome K. Jerome, whose special genius allies him much more with American humorists than his English brethren of the farcical pen, there is an excellent description of how some of the certificates with photographs for antifat remedies are obtained. Every physician knows how difficult it is for both patient and physician satisfactorily to treat obesity, once it has begun to become a serious factor in life. The number of photographs that have been published then of people "before and after using" where success from some anti-obesity remedy seems assured, have been a source of no little mystery to the regular profession. The charlatans appear to succeed where the regulars fail. Mr. Jerome's explanation throws much light on the subject, however, and comes very near solving the whole mystery of the supposed efficacy of drugs that careful analysis has, over and over again, shown to possess no special merit as antifat remedies, being only simple familiar drug combinations, as a rule, little likely to correct a serious fault of metabolism.

Mr. Jerome introduces one of the principal characters in his story, "The Beginnings of William Clodd," in a recent number of *The Saturday Evening Post*, Philadelphia, in this way:

Mrs. Postwhistle sat on a Windsor chair in the center of Roll's Court. Mrs. Postwhistle, who, in the days of her hebehood, had been likened by admiring frequenters of the old Mitre in Chancery Lane to the ladies, somewhat emaciated that an English artist, since become famous, was then commencing to popularize, had developed with the passing years, yet still retained a face of placid youthfulness. These two facts, her youthful placidity in middle age and her generous rotundity, taken in conjunction, had resulted in an asset to her income not to be despised. The wanderer through Roll's Court this summer afternoon, presuming him to be familiar with current journalism, would have retired haunted by the sense that the restful looking lady on the Windsor chair was some one that he knew before. Glancing through almost any illustrated paper of the period, the problem would have been solved for him. A photograph of Mrs. Postwhistle, taken quite recently, would have been encountered with this legend, "Before Use of Professor Hardtop's Certain Cure for Corpulency." Beside it a photograph of Mrs. Postwhistle, then the youthful Arabella Higgins, taken twenty years ago, with the legend below slightly varied, "After Use of Professor Hardtop's Certain Cure for Corpulency." The face was the same in both cases, the figure, there was no denying it, had undergone decided alterations.

This gives an excellent explanation of many things that before seemed inexplicable. It is even better than that other explanation, furnished some time ago, by the publication of requests for testimonials in which it was stated that every one who sent a good testimonial for a certain medicine would receive a mantel clock, or any other prize that he might select from a list furnished by the proprietors. The premium habit has spread from the tea and coffee stores to the patent medicine establishments. It is an amusing study in psychology, however, to see whom the patent medicine managers select as the best people to secure testimonials from. Prominent clergymen, Senators, Representatives, judges and prominent actors, jostle one another on this stage, where the only thing needful is a good capacity for self-suggestion and autodelusion and a reasonable desire to annex a certain amount of the more or less easily earned money of the patent medicine man, in order to help him in still further securing the patronage that enables him to pay so well. A psychologist has recently written on the psychology of advertising. This field of the patent medicine man presents more opportunities for original research of the most interesting kind than any other that we know.

STELLWAG'S SYMPTOM ON THE STAGE.

For those who are interested in neurology, and especially external eye appearances in relation to certain nervous diseases, there were some very interesting observations to be made at the Vaudeville theater, where a French company was playing. Madame Wiehe, who took the principal characters, gave in a pantomime an imitation of a doll. For many minutes after being taken from the box in which the doll is supposed to have been shipped from France, even the most careful observation does not show any movement of the upper eyelids. It is usually said that there is an involuntary winking of the lids about every ten seconds. An initial symptom of Basedow's disease, first described by Stellwag, and often called Stellwag's symptom, though occasionally his name is associated, especially in countries other than Germany, with the so-called lagophthalmos, or hair eye, the inability of the patient to close the eyes completely, is the absence of winking over long

periods in the exophthalmic eyes. It is not in the most severe cases of exophthalmos that the winking is rarest, but there seems to be some interference with the nervous mechanism controlling the motions of the lids.

Usually it is considered impossible to control the movements of the lids, so as to prevent involuntary winking. The French actress seems, however, to have succeeded in training her lids so as to control their movements. At first the persistent stare of the eye is so marked that one is tempted to think that perhaps some preparation like collodion is applied to the upper eyelid, so as to help in preventing the involuntary nictitation. As, however, the man in the case is a Pygmalion, who succeeds in putting life into the doll, as the lovesick Greek sculptor did into his Galatea, there is some very lively winking of the eyes a little later, and yet, before the end of the piece, the doll, for purposes of her own, relapses into the first stage of more or less inanimate doll life and the winkless stare returns again.

The last of the short plays that ran at the Vaudeville, by the way, was by a Viennese physician, Dr. Arthur Schnitzler, whom many American medical students in Vienna have met during their residence in that lively city. The piece is distinctly French, and is sometimes said to out-Herod Herod in the matter of its Frenchiness. This is, perhaps, one of the reasons why it has been given the honor of adaptation into French and the introduction to a Parisian audience in this guise.

MEDICAL BIGOTRY.

It is the custom to think that bigotry belongs only to religious controversy and does not invade the field of scientific discussion. The *odium theologicum* is apt to be especially bitter, but it must not be forgotten that the *odium medicum* does not yield much to it in acerbity, and may do great harm. Some striking examples of it are furnished in the recent book on Hypnotism, its History, Practice and Theory, by Dr. J. Milne Bramwell, of Edinburgh, who is very well known as the author of a number of articles on the theory and practice of hypnotism. This book is published by the Lippincott Company, Philadelphia.

In English-speaking countries, at least during the first half of the nineteenth century, an interest in hypnotism on the part of a serious medical practitioner, and especially one whose talents and skill had procured for him a practice as a consultant, was almost sure to be followed by the loss of consultations. Three names particularly stand out in English medical history in this regard—they are Elliotson, Esdaile, who did his work in Calcutta, and Braid, who is very well known as the most authoritative early English writer on hypnotism.

"In 1831, Elliotson was appointed Professor of the Practice of Medicine at University College. His connection with that institution and the commencement of his mesmeric researches were described in the *Medical Times* by the writer already referred to, and I again quote the latter almost in his own words. Thus, he said, on the establishment of the University of London, or, as it is now called, University College, Elliotson moved there, as to a temple after his own heart, and devoted himself enthusiastically to its interests. He was all for the College, was its great impelling force, and worked for it with an alacrity and energy that explain much of its early progress. The hospital may be said to have been mainly his erection. Yet here, in the home of his labors, the scene of his triumphs, he received his greatest check. Dupotet's visit to this country attracted much attention to mesmerism, and led Elliotson to investigate the subject. His experiments were successful, and believing that he had found an opening into an unexplored science, he pursued them with zeal and daring enthusiasm. His reckless independence made him many enemies and official opposition to mesmerism led him to resign his hospital appointments. Notwithstanding this, Elliotson adhered to mesmerism and sacrificed to it friends, position and practice, but still looked forward to the hour when the profession would say of it, as of creosote, iodide of potash, prussic acid, auscultation, etc.: 'Useful novelties if properly employed.'" Elliotson was really, however, one of the most progressive medical men of his time.

"The *Lancet* pointed out that it was he who had shown how the heart sounds were influenced by posture, and had also drawn attention to many other hitherto unnoticed phenomena connected with auscultation. Elliotson, in fact, was the earliest to use the stethoscope in England and began to do so immediately after the publication of Laennec's work. At first he made his observations quietly in his hospital wards, but, as soon as he drew attention to them, he was ridiculed and abused. The stethoscope, as well as the facts of percussion and auscultation as described by Auenbrugger, were condemned as fallacies by the foremost teachers of medicine in London, while even at a much later date, they were treated at St. Thomas's with indignation or silent contempt. At the College of Physicians a senior fellow, in a Croonian Lecture, denounced the folly of carrying a piece of wood into a sickroom. Another condemned the stethoscope as worse than nonsense, and said: 'Oh, it's just the thing for Elliotson to rave about,' while a third, on seeing one on Elliotson's table, said: 'Ah! Do you use that hocus pocus?' On Elliotson replying that it was highly important, he added: 'You will learn nothing by it, and, if you do, you cannot treat disease the better.'

"In 1846 Elliotson's turn came to deliver the Harveian oration, but, as soon as it was known that he had accepted the office, he was attacked in the most savage manner, in order to prevent his appearing. For example, the *Lancet* called him a professional pariah; stated that his oration would strike a vital blow at legitimate medicine, and would be a black infamy degrading the arms of the College.

"Undeterred by this," continues Milne Bramwell, "Elliotson made mesmerism the subject of his address. Without referring to the attacks which had been made upon him he simply stated the result of his researches, and respectfully invited the College to examine alleged facts of overwhelming interest and importance. He exhorted his hearers to study mesmerism calmly and dispassionately, and reminded them with more truth than tact, that all the greatest discoveries in medical science, and the most important improvements in its practice, had been opposed by the profession in the most violent and unprincipled manner. As examples of scientific discoveries which had been received in this way, he cited those of the lacteal vessels, the thoracic duct, the sexual system of plants, the circulation of the blood, the sounds of the chest and their relation to the diseases of the heart and lungs and their coverings, etc. As instances of improvement in practice which had been treated in like manner, he referred to the employment of Peruvian bark, inoculation and vaccination for smallpox, the use of mild dressings, instead of boiling oil, in gunshot wounds, the ligature of the bleeding vessels after operation, instead of the application of burning pitch or red-hot irons, etc. We should, Elliotson said, never forget these things, nor allow authority, conceit, habit or fear of ridicule to make us hostile to truth. We should always have before our eyes that memorable passage in Harvey's works: 'True philosophers, compelled by the love of truth and

wisdom, never fancy themselves so wise or full of sense as not to yield to truth from any source and at all times; nor are they so narrow-minded as to believe any art or science has been handed down in such a state of perfection to us by our predecessors that nothing remains for future industry.' All this, Elliotson said, should be borne in mind when considering the alleged facts of mesmerism. In his opinion many of these were indisputable; for ten years he had shown how mesmerism could prevent pain during surgical operation, produce sleep and ease in sickness, and even cure many diseases which had been unrelieved by ordinary methods. It was the imperative and solemn duty of the profession carefully and dispassionately to examine the subject. He, therefore, earnestly implored them to do so, if they cared for truth, their own dignity and the good of mankind."

Dr. Bramwell shows how the great Braid shared the obloquy of those interested in hypnotism. Braid frequently referred to the almost incredible opposition he had to combat, both at the hands of the orthodox medical practitioner, and of the mesmerists. His explanation of this is given in his own words:

"'Throughout the whole of my inquiries my chief desire has been to arrive at what could be rendered most practically useful for the relief and cure of disease; and I hesitate not to say that, in the hands of a skilful medical man, who thoroughly understands the peculiar modes which I have devised for varying the effects in a manner applicable to different cases, hypnotism, besides being the speediest method for inducing the condition, is, moreover, capable of achieving *all* the *good* to be attained by the *ordinary mesmerizing processes,* and *much more.* . . . Like the originators of all new views, however, hypnotism has subjected me to much contention; for the skeptics, from not perceiving the difference between my method and that of the mesmerists, and the limited extent of my own pretensions, were equally hostile to hypnotism, as they had been to mesmerism; and the mesmerists, thinking their craft was in danger—that their mystical idol was threatened to be shorn of some of its glory by the advent of a new rival—buckled on their armor, and soon proved that the *odium mesmericum* was as inveterate as the *odium theologicum.*'"

The third of the group of English medical observers to suffer from interest in hypnotism was Esdaile. In March, 1852, Esdaile published a pamphlet on The Introduction of Mesmerism as an Anesthetic and Curative Agent into the Hospitals of India, which he dedicated to the members of the medical profession. In this he complained bitterly of his treatment by the editors of different medical journals and of their determined attempt to suppress all evidence in favor of mesmerism. Professor J. Y. Simpson, of Edinburgh, had written to Esdaile to the effect that he owed it to himself and to his profession to let his proceedings be known in England. In response to this Esdaile sent an account to an English medical journal of 161 scrotal tumors removed during mesmeric trance. The history of what followed, and Esdaile's opinion of the treatment he received, shall be given in his own words:

"'My article was not published, and I then sent a more general paper containing a résumé of my surgical work. This was rejected for its *unproctical character!* I have heard that it is given as a reason for not printing my paper that, though no one now denies my facts, these apply to the natives of India only. But, as far as I know, no medical journal has admitted the reality of *painless mesmeric operations,* even for India, or inserted one of the numerous European cases reported from London, Paris, Cherbourg, etc. They will not admit, or permit you even to hear of, such indisputable facts, through fear of the consequences.'"

OPTIMISM.

Physicians who find patients discouraged under the weight, only too often, of imaginary woes, and who wish to arouse them to some sense of how good the world may seem even under the most trying circumstances to a really grave spirit, should prescribe the reading of Miss Helen Keller's little book on Optimism, which has recently been published by C. P. Crowell & Co., in New York. Most physicians know the story of Helen Keller very well. As the result of one of the infectious fevers in childhood she became blind, deaf and dumb. Notwithstanding this she was graduated with honors from college and university, and has written an autobiography that is one of the most interesting of human documents. The present volume is an essay in which she shows how many are the bright things in life for her, notwithstanding her apparently insurmountable infirmities. A good example of how she is able to bring darkness out of light is contained in the following sentences:

"When I learned from Berkeley that your eyes receive an inverted image of things which your brain unconsciously corrects, I began to suspect that the eye is not a very reliable instrument after all, and I felt as one who had been restored to equality with others, glad, not because the senses avail them so little, but because in God's eternal world, mind and spirit avail so much."

As a reviewer in the New York *Independent* said: "Nothing can be finer under the circumstances than this assertion, made so simply, and with such an air of personal conviction. In fact, one of the remarkable features of this essay is the experimental note in it, as if the writer had tested intimately every high doctrine she holds. Her philosophy is not the expression by rote of a person who has been well taught, but it is wisdom she has learned of her own volition and fitted to the bright heart of her darkness, a sort of psychic illuminating of her own mind. And in her vision of things there is no evidence of prejudiced deafness, and in the eloquence of her optimism no hint of dumbness."

AUTOMATIC DRAWING.

The peculiar things that may happen under pathological conditions of mentality have evidently not all been exhausted. A few years ago a young girl at the Salpetriere wrote some very curious, but absolutely unintelligible messages. Notwithstanding the failure to understand them she continued to write, and as this was the only means of expression she had in her deeply hysterical condition every effort was made to solve the riddle of the writing. Finally it was found that it was really mirror writing—that is, ordinary letters written in back hand and from right to left, such as Leonardo da Vinci, for some curious but unknown reason, employed in certain of his scientific manuscripts, wishing perhaps to conceal his original discoveries from those of his generation who might care to employ them for their own advantage or develop them for industrial applications, without giving their inventor due credit. Since the case of the Salpetriere girl a number of other cases have been recorded in which mirror writing was one of the symptoms. Just what curious functional disturbance of the cerebrum and the connecting neurons brings it about is indeed hard to understand.

In the January number of the *Popular Science Monthly,* Professor William James, Professor of Psychology and Philosophy at Harvard University, gives some details of a case of automatic drawing. The subject in this curious experience made peculiar draw-

ings of whose outline he was almost unconscious himself, apparently as the result of the guiding power of a secondary personality. These drawings, which are mainly quaint portraits of human beings, all have a certain similarity of type and this type is utterly unfamiliar in any other connection to the person whose hand is used in making them. The subject says: "My hand executed these without volition or direction from my natural self. My mind directed neither the design nor the execution. A new power usurped for the time being the functions of my natural or every-day mind. Many times I tried to produce pictures of familiar faces, or scenes familiar to me by long association. I could produce nothing in this direction, but confusion was the result of the attempt. My hand continued to be guided by the unknown power. Weird, fantastic pictures were produced in abundance, many of them artistic in execution, but mostly of ancient type.

"Sometimes the face would be so covered with strange devices as scarcely to be recognized as being intended for a face. Frequently a rock would be drawn with faces hewn in it. While drawing these pictures I became drowsy, so much so that after finishing an artistic one, I would sometimes go into an hypnotic sleep, and always would, after a long sitting, if I did not combat the influence. My pencil sometimes moved so rapidly as to make it difficult to follow it with my eye, at other times it moved slowly. Some of the best effects were produced by rapid movements. I never knew what my pencil would make when it commenced, and often did not know until finished. Sometimes a design would be entirely changed.

"Small pictures were frequently produced by a few rapid movements of the pencil from side to side, the pencil apparently not being lifted, yet the features of the face and general contour of the subject in hand would appear plainly. Voluntary suggestion has little effect on the drawings. After repeated suggestions, I have sometimes been able to obtain an allegorical picture, as for instance, when I asked for a message from my son, who resided at a distance, a carrier pigeon, having a ribbon around its neck with a letter attached, was produced.

"I have tried hard to account for the power or directing mind that produces these pictures, but so far with no satisfactory result. I must say, however, that evidence to me is strong that, in order that the unknown power should have sway, the natural or earthly mind must be for the time being set aside, either entirely, or (what seems to me more reasonable), the unknown power is the dominant one, but acts in conjunction with the earthly mind. Although while drawing, I feel more or less drowsy, my senses seem in some respects to be very keen. To my eyes the pictures usually appear highly exaggerated in beauty as well as distinctness."

New Method of Identifying Human Blood.—A valuable observation, made by H. Marx and E. Ehrenroth (Münch. med. Woch., Feb. 16, 1904), may be destined to replace the more complicated serodiagnosis in identifying human blood. The two authors discovered that if foreign serum is added to human blood, a rapid and complete agglutination of the erythrocytes occurs, while with homologous serum they are hardly influenced. The serum of monkeys behaves like homologous serum, except that the cells shrink and become polygonal instead of crenated. The technic is extremely simple: the suspicious blood is dissolved with a very small quantity of normal salt solution, mixed with a loopful of blood taken from the finger-tip and examined with the low power for the next fifteen minutes. Numerous tests gave as accurate results as serodiagnosis.

SOCIETY PROCEEDINGS.

THE SOCIETY OF THE ALUMNI OF CITY HOSPITAL.

One Hundred and Twelfth Stated Meeting, held February 10, 1904.

Hemorrhagic Diseases in Children.—This paper was presented by Dr. William L. Stowell. He stated that purpura is not a disease in itself, but the outward manifestation of a group of conditions not yet well understood. It signifies purple spots of hemorrhagic origin which occur in the skin upon mucous membranes and indeed upon all parts and organs of the body. It may seem to be due to one of the following: (1) Vasoneurosis, as in locomotor ataxia; (2) a drug, as iodide of potash; (3) an infectious disease, as diphtheria or smallpox; (4) a diathesis, as in rheumatism; (5) a special germ; and, lastly (6) a toxin, as in enteritis, following the ingestion of tainted food. The author cited a series of cases from which he deduced the following conclusions as to the indications for treatment. Of maximum importance, probably, is the proper management of the feeding of these patients, orange or lemon juice being frequently called for. Calcium chloride increases the coagulability of the blood and tends to check the hemorrhages. Vegetable acids and arsenic are useful. Among the newer drugs stypticin and suprarenal gland stand first; a number of cures of intractable cases having been reported through the use of these drugs. Adrenalin probably is our best drug. In conclusion, he stated that a specific germ is not yet demonstrated for all cases.

Dr. R. C. Newton said that young children possess very low resisting powers to bacteriological toxins. He asked the essayist whether he had not found it frequent for fatal cases to have persistent vomiting. Dr. Stowell replied that they invariably did vomit, if the infection was located in the gastro intestinal tract. Smith has reported 49 such cases. Dr. Newton believed that the persistent vomiting was probably an effort on the part of nature to get rid of the toxins.

Dr. Gessner Harrison reported a case in which the trouble had started from a scratch under the tongue. Infection was followed by a purpuric eruption. The patient recovered.

Case of Purpura due to Gastro-intestinal Disturbance with Final Recovery of the Child.—Dr. A. A. Moore reported this case. Another case had come under his care which had been mistaken for cerebrospinal meningitis. There were purpuric spots on the chest and abdomen, besides hemorrhages into the mucous membranes of the mouth. On autopsy, hemorrhages were found in the gastric mucous membrane and at the base of the brain.

Dr. A. Rupp cited a report whose author had investigated a number of these cases occurring in Italy. According to this author purpura was followed by icterus simulating yellow fever. Some cases show a waxy degeneration of the intima of the arteries.

Dr. R. Waldo had seen a number of cases in which the family history of the patient was decidedly tainted with tuberculosis and cerebral hemorrhage. In some people the onset of purpura may be extremely sudden. It is quite possible for such cases to be the victims of cerebral hemorrhage.

Dr. Oppenheimer cited a case of purpura which had followed a diphtheritic throat. Later the right eye grew black and in time sloughed out. The same condition developed later in the left eye, and was treated by incision. Sight was not preserved but light perception remained.

Dr. Terriberry had seen one case in which the pur-

pura had followed syphilis and had disappeared under anti-syphilitic treatment.

Dr. Stowell, in closing, said that the unusual fetor of the stools was due to hemorrhage from the mucous membrane of the gut. Authorities were much confused as to the etiology of hemorrhagic diseases in childhood, no definite knowledge being at hand up to date. One or two writers had believed that there were definite changes in the intima of the arteries and that the blood broke through the arterial wall directly into the tissues. He agreed with Dr. A. Jacobi that the three diseases, scurvy, purpura and hemophilia were manifestations of the same condition.

Abuse of the Uterine Curette.—Dr. Ralph Waldo said that he did not wish to criticize the legitimate use of this valuable instrument, but he felt it wise to direct the attention of the Society to the fact that it is used too freely and in an improper manner. This he ascribes to the fact, first, that the indications for its use are not properly understood, and second, that a positive diagnosis is not made before operation is undertaken. He confined his attention solely to those cases in which pregnancy had recently existed and in which the uterus had been partially or completely emptied. He said that there were but two legitimate uses for the curette under these conditions; one is to utilize the instrument as a sound for exploration, the other to employ it for the removal of foreign material. A sharp instrument should never be used for these conditions. If the body of the uterus is found to be abnormally large, it can usually be thoroughly emptied without the use of an anesthetic. The author emphasized the necessity of thoroughly and completely emptying the uterus at one sitting, repeated employment of the curette being strongly contraindicated. He believed that it is better to do nothing at all than to use a sharp curette and to partially remove the offending material, because this simply opens a way for the entrance for septic material.

Dr. W. Ridgely Stone said that it appeared that Dr. Waldo had unintentionally omitted to mention that the chief reason for the uselessness of the curette in cases of streptococcic infection was that the streptococci did not lie upon the surface of the infected mucosa, but were deep down in the lymphatics, far beyond the reach of the instrument.

Dr. A. A. Moore said that in examining 1,200 histories of cases of this character, he had found no mortality, whenever no instrument whatsoever had been used. From this he had concluded that no instrument, not even a dull curette, should be employed. He advised the use of saline irrigations and rectal enemata in the treatment of these cases.

Dr. C. G. Child preferred to use his finger to establish the diagnosis of the presence of retained secundines. Most infections he believed to be due to dirty instruments, clean instruments never being harmful when introduced into the uterine cavity. Sharp curettes, he declared, had never done harm in his hands, nor would they in the hands of others, if properly used. The patency of the cervical canal could not be considered a reliable sign of retained membranes, as this was most frequently caused by laceration of the internal os. A large number of the cases of profound sepsis were, in his opinion, due to the puncture of the uterus by a dirty curette, this lesion being usually brought about by a faulty technic.

Dr. R. C. Newton said that for years he had been in the habit of using the sharp curette in cases similar to those under discussion and had invariably met with admirable success.

Dr. Waldo, in closing, said that if the lochia were offensive, and whenever there was reason to suspect that some portion of the membranes were retained, the curette was indicated. His opinion as to the danger of the sharp instrument was unaltered. He declared that if the curette had never been invented, there would have been fewer deaths, most cases of sapremia recovering without operative intervention.

NEW YORK ACADEMY OF MEDICINE.

Section on Genito-urinary Diseases.

Stated Meeting, held February 17, 1904.

The President, James Pedersen, M.D., in the Chair.

Presentation of Pus-kidney and Ureter.—Dr. J. B. Bissell presented this specimen which was removed from a man, forty-four years of age, at St. Vincent's Hospital last December. The following history was given. He was a man of very intemperate habits and had been in the hospital two or three months previous for treatment of alcoholism. He had had repeated attacks of urethritis and, two years ago, was operated upon in Chicago for a very tight stricture of the deep urethra, perineal section and drainage being followed by a good result, but this was neglected, no sounds being passed or any after-treatment being followed. In the hospital he was turned over to the surgical side from the medical because of an attack of cystitis. Before coming in very small instruments could be passed. Under gas anesthesia a filiform went through and the urethra was dilated a slight amount. It bled a good deal and was hard to dilate. Temperature and pain suddenly developed and he was unable to sleep. The urine being filled with pus perineal section was performed and it was with difficulty that he was able to cut through the perineal floor because of the dense cicatricial tissue. At the end of two or three days after the operation the temperature rose to 103° F. and stayed there; there was severe pain over the abdomen, more especially about the umbilicus and in the region of the bladder. The high temperature and bad pulse continued. The urine contained albumin and all sorts of casts. There was no pain in the left kidney. The patient died and, as no autopsy was allowed, the specimen was obtained surreptitiously. The kidney was shown to be filled with pus, without any kidney tissue left except the capsule and some fibrous tissue dividing in a general way the pyramids. A large tumor was found between the bladder and rectum which ruptured under examination and from which came a great deal of pus. It was an abscess. Cutting off the ureter from the kidney two fingers could be introduced into the cavity of the ureter, which was about one inch in caliber; the tube ran down through the abscess cavity and then into the bladder and its potency had been occluded at its junction with the bladder by the pressure of this abscess.

Dr. George E. Brewer said he was reminded of a couple of similar cases seen last summer within one week of each other. One case had been treated for many months for malaria, the diagnosis being made because of a supposed enlarged spleen, chills every day, with temperature ranging from 100° to 105° F. and followed by sweating. The oval renal tumor on the left side was taken for an enlarged spleen. The blood count gave 30,000 leucocytes. A primary nephrectomy was performed. The kidney contained over 1½ pints of pus. Within one week of this he saw another case, one of puerperal infection. The trouble in the kidney was for a time overlooked. There was an acute sepsis, the symptoms somewhat resembling those of malaria. The renal tumor was about the size of an infant's head, was movable and very tender to pressure. The operation was a difficult one on account of the size of the

kidney and adhesions. It was incised and drained before it could be delivered. Both cases made satisfactory recoveries.

Dr. Edward L. Keyes, Jr., was reminded of a case quite the opposite from that referred to by Dr. Brewer. This patient had a very large kidney, which was not palpable, although it discharged a pint or more of thick pus in twenty-four hours. The patient was very stout, and this perhaps accounted for the fact that, although the loin was tender, no tumor could be felt. It is astonishing how large a tumor may exist in the loin and yet be impalpable.

Foreign Bodies in Perineum.—Dr. John F. Erdmann presented parts of two needles which he had removed from the perineum of a male about two weeks ago. The patient was thirty-two years of age and contracted gonorrhea from his wife. Three years ago he was operated upon for a deep stricture, the perineal operation being done. At that time he was told that a needle had been left in the wound. A year or so afterward, having an irritation in the urethra, he was cystoscoped and a large tumor of the bladder diagnosticated. A suprapubic operation was performed for purposes of exploration and nothing found. The wound was allowed to close. He was then treated for a profuse suppuration, pus passing by way of the meatus, and a fistula occurred in the center of the perineum. The pus was charged with gonococci and the fistula in the right buttock communicated with the urethral canal. The needle was supposed to have been left in the perineum. In passing a sound Dr. Erdmann felt it slip as if over the triangular ligament. Later he got a metallic grate and therefore did a perineal section. In trying to cut through the knife suddenly stopped, evidently having struck the needle. The parts were stretched and three small portions of the needle, broken during the attempt, were removed. While retracting the wound he found a large arc of steel minus the eye. Patient was doing well and was without further symptoms. Dr. Erdmann said it was strange to find parts of two needles which had been left in the wound at one operation.

Dr. Eugene Fuller said there had been a man in the City Hospital who had been operated upon four or five times in the attempt to close a spacious perineal fistula. He did a very extensive plastic operation and felt very proud because he closed the fistula. The man was quite comfortable for some time after, when frequency of urination developed. On making an examination a short time ago, he struck a large Hagedorn needle in the deep part of the urethra. It had evidently been broken off at some early operation. He tried to remove it through the urethra but could not and felt justified in temporarily leaving it, hoping it would work to the surface. He was averse to cut through the perineum, unless positively necessary, because the tissues were so badly nourished that he feared non-union of a fresh incision might result in the production of a fistulous tract.

Dr. Beck referred to Hyrtl's book on comparative anatomy, in which were shown foreign bodies, especially needles, in the perineum and bladder. He emphasized the importance of taking X-ray pictures in obscure cases; by so doing it was wonderful how often some unexpected information could be had by a study of the skiagraph. He could report many cases of this kind. In cases of calculi in the bladder, although the sound would reveal more than the X-ray in one way, still the latter gave excellent additional information regarding the size and number of stones in the bladder. He thought it would always pay the specialist to take skiagraphs.

Dermoid Cyst and Vesical Calculus.—Dr. Edward L. Keyes, Jr., presented these specimens. The patient was twenty-four years old and had suffered from various troubles for four years. Before this time she had some dysmenorrhea. The sickness began with an abscess said to be in the left ovary. Operation was suggested and refused, and the abscess burst into the intestine. She then suffered from alleged colitis and had many febrile attacks, sometimes called malaria and once attributed to typhoid. The malarial attacks lasted unduly long, while the typhoid was remarkably short. She then developed cystitis and, about a year ago, began to pass small stones from the bladder. These were said to come from the kidney; and when she exhibited two larger ones formed upon hairs, she was told that she had swallowed the hairs. This, in spite of the fact that examination revealed that every one of the many stones she had passed had a hair for nucleus. Last April litholapaxy was performed and the urethra stretched for digital examination. After the operation she was told that her stones were all gone, and when, ten days later, they again reappeared, she was informed that the urethra had been dilated in order to permit these stones to pass readily. She came into Dr. Keyes' hands last fall; and cystoscopy revealed two stones attached to the bladder above the right ureteral orifice. Laparotomy revealed a dermoid cyst absolutely incorporated in the pelvic wall by dense adhesions—the result of previous inflammation. The cyst could not be enucleated and so was opened. He shelled out the growth which presented. No attempt was made to close the openings into the bladder and the bowel. Drainage by a tube above and a permanent catheter below. Recovery was uneventful, except for a scare caused by the passage of three small stones three weeks after the operation. These had undoubtedly been overlooked at the time. She has passed no other stones in the twelve weeks since operation. Although she had passed gas from the bladder from time to time during the past year, the vesico-intestinal fistula closed at the end of three weeks; reopened for a week in January and has been closed ever since. She is now entirely well, except for the incontinence of urine which returned two weeks ago after a severe fall. This incontinence is apparently neurotic. Specimens of the cyst and of calculi dependent from hairs were shown.

Case of Hematuria.—Dr. Alfred T. Osgood reported this case for Dr. F. Tilden Brown, who was unable to be present. The patient was a man, seventy years old, whose father died of cancer of the tongue and his brother of pulmonary tuberculosis. There was no history of nephritis or of hemophilia in the family. The patient had not used alcohol for twenty years and had never had any venereal disease. Previous history was good. In 1898, for seven or eight months, he had attack of colicky pains localized in the bladder region, which was thought to be intestinal. No blood was noticed during this time in the urine. Never had pain referable to either loin, testis or thigh; no chills or fever. The following eight weeks he was without pain. Then, at urination, the stream suddenly stopped with a sharp cutting sensation in the urethra and a rough oval stone, the size of a lemon seed, was removed from the fossa navicularis. This occurred in 1899, and he was perfectly well until November, 1903, when he noticed blood in his urine which continued to be present for a week. Some of the time clots in the bladder made urination difficult. One week later, after heavy lifting, the hematuria recurred and with it some pain in the bladder region and the passage of clotted blood. After resting a week the bleeding ceased but recurred on further exertion. Since Christmas the hematuria

had been constant but the patient no longer had the pain behind the symphysis and had passed no clots. No signs or symptoms were present beyond the passing of bloody urine. Various diagnoses had been made by different doctors. He was first seen by Dr. Brown January 5, 1904. The urine was passed voluntarily and had the appearance of blood; on allowing it to settle it was found to contain one-tenth to one-fifteenth of red sediment made up only of blood cells, the leucocytes being in the proportion of normal blood. On January 16 cystoscopic examination showed a practically normal bladder and ureteral mouths. Blood issued from the right ureter. On January 22 both ureters were catheterized and the urines obtained were presented to the Section. The urine from the left ureter was normal except for a faint trace of albumin. That from the right ureter showed blood. The catheter was passed to the pelvis showing that the blood originated there. Forty to fifty ounces of urine were passed each day. Two or three radiographs revealed nothing. The case was presented really as one for diagnosis.

Dr. Carl Beck said that if the skiagraphic picture was good enough to show the spinal column, the twelfth rib and the psoas muscle, one might be able to exclude nephrolithiasis; but if it did not show these structures distinctly the skiagraph could not be relied upon for this purpose. The clinical history of cases had shown that many shadows had been misinterpreted; a negative skiagraph had been proven to be at fault and a positive shadow made later by other operators; therefore, the skiagraph could be relied upon only if it was perfect.

Dr. Eugene Fuller referred to a case where the diagnosis made from the clinical symptoms was probably stone in the kidney. A skiagraph was taken and showed nothing at all. The patient went to another city, another skiagraph was taken and stone was beautifully shown as being in the pelvis of the kidney; the stone was the size of a small marble and well defined. He believed that to get good result a number of pictures must be taken and in different places. In many cases of hematuria one may expose the kidney and even then be at a loss to account for the bleeding. Oftentimes in doing this and tearing the capsule somewhat the bleeding will afterward cease.

Dr. Charles H. Chetwood reported a similar case before the Section about a year ago. The history of hematuria was given without symptoms of nephralgia or colic. The cystoscope revealed that the blood came from one ureter, the jet from the opposite side being perfectly clear. No attempt was made to do a double ureteral catheterization on account of the clearness of the cystoscopic demonstration. The flank was opened and the kidney exposed. A search was made for stone, but none found. The capsule was then split and the pelvis of the kidney was then opened, and still there was nothing abnormal seen in the gross appearance. A catheter was passed down the ureter, but no occlusion detected. In one portion of the kidney there was a small area a little more dense than the surrounding structure, and a piece of this was removed for pathological examination. Previous to operation the urine had been examined, but absolutely nothing abnormal found, otherwise than the presence of blood. The piece of tissue removed, upon examination, showed evidences of parenchymatous nephritis. This case demonstrated the fact that one may meet a case of profuse hematuria referable to the kidney without there being any lesion demonstrable upon gross examination of the kidney or by laboratory analysis of the urine. One of the most important features of this case was that, after decapsulation of the kidney, the hemorrhage absolutely ceased and was seen for months afterward without showing any return of the blood in the urine.

Dr. J. B. Bissell believed that the diagnosis should be held in abeyance until incision was made into the kidney. Until that had been done we could only speculate regarding the cause of the hematuria.

Dr. James Pedersen said that he remembered hearing Dr. W. T. Bull remark that a papillomatous condition of the pelvis of the kidney could exist and give rise to hematuria without any other symptom.

Dr. Carl Beck said that the skiagraph was absolutely unreliable and would not show whether a stone was present or not. He could appreciate the difficulties in taking such skiagraphs. The chances of getting better skiagraphs were increased by compressing the abdomen and pushing in the tissues as much as possible by a diaphragm and taking two or more pictures.

Operative Surgery Applied to the Seminal Vesicles: A Demonstration of Some New Principles.—Dr. Eugene Fuller read this paper. He said the inaccessibility of the seminal vesicles was such as to prevent pathological conditions there from being recognized except by those who paid especial attention to this field. In his experimental work his aim had been to discover, first, the best operative method to expose the seminal vesicles and, second, the appropriate surgical treatment for the different types of disease. The chief features of the operative technic (read in Feb., 1901, and published in May, 1901) were the knee-chest position and the extent of the lateral incision which allowed a free dislocation upward of the rectum. Seminal vesiclotomy was the term applied to the new surgical procedure. He had 21 cases which were subdivided into five groups. Group 1 consisted of extremely chronic cases of seminal vesiculitis in which the lesions consisted chiefly of sclerosed tissue, not only the walls of the seminal vesicles but the surrounding fibrous tissues with the result that the cavities of the seminal vesicles were contracted and the sacs bound down by adhesions. Six of his cases were of this group, and in four his results were good, in two negative, as far as the removal of clinical symptoms were concerned. Group 2 consisted of cases of seminal vesiculitis less chronic than those of Group 1. The intravesical catarrh was still a prominent feature and there was no contraction of the sac cavities; in fact, in some there was an atonic distention of the sac cavities. Eight of his cases were of this group and three had been discharged in satisfactory condition and he expected they were cured by the operation. Of the remaining five good results positively followed in three; two cases were lost sight of. Group 3 consisted of cases of acute diffuse periseminal vesicle abscess with gonorrhea as the infective agent. All results were good in this class. In Group 4 the lesion was an adenoma which involved the wall of the seminal vesicle causing an obliteration of the sac cavity to a large degree. The result after removal was good. Group 5, the lesion was tuberculous involvement of the seminal vesicles and removal of the sac caused only temporary relief. A sinus persisted and the patient died through extension of the tuberculous process. Then followed a detailed recital of the cases. His results were such as to warrant him in advocating this treatment in many cases of Group 1, some in Group 2, and in all cases of Groups 3 and 4. In Group 5 nothing was gained by operation. For the liberation of pus in this region the operation under consideration he believed to be better than those in vogue, *i.e.*, perineal section, with a median incision through the trigonum; incision through the rectal wall; perineal incision through the prostate.

Dr. Chetwood has had no personal experience in

operating upon the seminal vesicles, and his knowledge of the subject was obtained largely from its literature. As a result of such reading, it seemed to him that one of the principal questions at issue was the route and technic to be selected, of which there were various modifications and, like operations upon the prostate, some adopted a supra and others an infra means of approach. The method of Drs. Duval and Daudet approached the seminal vesicle through the inguinal region and claimed to obtain by this technic a satisfactory view. With the purpose of enlarging the field in reaching the vesicles and adjacent organs, this operation was modified by Young, of Baltimore, who advises suprapubic cystotomy with a large incision augmented by a lateral one. The perineal operation, on the other hand, has been modified by the addition of a supplementary sacral flap, after Kraske and Schlange, as favored by Koenig and others. A casual observer would be inclined to believe that the perineal incision for approaching the vesicles is the one of choice for drainage purposes. In case, however, of extensive lesions, tuberculous or otherwise, it seemed as though it were necessary to perform one of the operations which enlarged the field of vision; such as that of Young by the suprapubic route, or the perineal operation supplemented by the sacral flap. Dr. Chetwood had experimented upon post-mortem subjects, and had found that Young's method gave an ample view of the parts. However, after hearing Dr. Fuller's array of successful cases, his method must be accepted as being satisfactory for a large proportion of cases; even though there was extensive involvement of the parts and a very radical operation was undertaken.

Dr. J. B. Bissell said that none of those present probably had had an opportunity to operate upon such cases and watch the results as Dr. Fuller had. He agreed entirely with what had been said regarding the non-operative interference with tuberculous disease of the genito-urinary organs, and particularly of the seminal vesicles. Such interference usually made the condition worse. He thought the method described in the paper to be a very satisfactory one but, like Dr. Chetwood, he had never performed that special operation. But, in order to reach the seminal vesicles satisfactorily he thought that of Zuckerkandl's incision and next that of Dr. Fuller's to be probably the most available. He said he was puzzled regarding the question of diagnosis and also the prognosis of disease of the seminal vesicles.

Dr. James Pedersen said he had had the opportunity of seeing Dr. Fuller operate on one or two of his cases and he could say that his method for reaching the seminal vesicles was a very good one, especially in Dr. Fuller's hands.

Dr. Eugene Fuller said that he hoped others would try to do work in this direction because there were many cases in need of relief to make them able-bodied floating around from one hospital to another, all of whom were ready and glad to be operated upon to get relief. He said he had been satisfied with the results he had obtained and felt that he had accomplished a great deal for this class of sufferers. His first five cases he had watched for over a year and then he made his preliminary report announcing the results. After getting evidences on the findings of these first five cases and finding them quite satisfactory he then started in to do more operative work of this nature. So far as the routes were concerned, most of them were too serious operatively to be thought of, the one through the bladder was not practical, as the seminal vesicles cannot be reached readily in that way. The operation of going through the abdomen and depressing the bladder was an awful operation, especially when done upon a tuberculous patient. The operation he advocated took less than fifteen minutes and none of his cases, now numbering 21, gave dangerous symptoms. The Kraske and Rydygier operations, cutting across the sacrum, were all capital operations and left the patients, as a rule, for a long time in a serious condition. It was usually six months or more before these patients were well. The incision he made was a freer one and he dislocated the rectum upward and out of the way. The diagnosis of these cases he said was usually made by rectal feel and required a well-trained sense of touch. With an educated finger one could readily map affairs out well, but it required practice. This tactile sense should be practised upon both normal as well as diseased conditions. Most people confounded prostatitis and seminal vesiculitis—two entirely separate affections. There was no surgical reason why patients should not get well after his operation of seminal vesicotomy any more than after cystotomy in certain cases of cystitis. The surgical principles which he had applied to the seminal vesicles were new only in so far as the seminal vesicles were concerned. In connection with the urinary bladder, the renal pelvis and the gall-bladder they had been long applied.

Dr. Carl Beck said that in the October meeting of this Section a case had been reported by Dr. Lilienthal with the title "Deformity of Penis Resulting from Operations for Relief of Hypospadias." According to this report it was said that "the first operation performed upon him was a Beck, and it appeared as if, when the urethra had been drawn through the anterior part of the glans and stitched there, it had sloughed, and as it descended it had seemed to have drawn with it a portion of the glans, etc." Dr. Beck had written Dr. Lilienthal before the last meeting and asked for a correction of this statement. In the article it was also written, "a deformity which had followed ten previous operations for the relief of hypospadias." "When first seen by Dr. Lilienthal the deformity was such that it was difficult to recognize the organ as a penis." Dr. Beck said he had not operated upon him ten times, but only four, and that the first operation was for a penile hypospadias of moderate degree. It is only in such cases that he advises his method of anterior dislocation, originally advised for the balanic type only. He does not advise it in the severe penile type, because the distensibility of the penis has its limits. He was afraid the usefulness of the operation had been much impaired through this report in the Medical News (December 5, 1903). The truth of the matter was that after having operated upon this patient at St. Mark's Hospital the patient the next morning took a pocket knife and cut off the catheter in the urethra and therefore caused a failure. Another plan of operation was now considered. Although the patient was circumcised and had only a small portion of a prepuce left, Dr. Beck dissected through, turned it back and implanted it in such a way that it could be used later for the formation of a new urethra. After the bridge was dissected and a flap from the scrotum formed, in order to cover the new urethral canal, the patient insisted upon leaving the hospital. The patient signed a paper stating that he knew that he would injure himself by getting up and left the institution against the doctor's advice. In the article mentioned it was stated that "When Dr. Lilienthal first saw him, a portion of the glans appeared as an isolated fragment, entirely separated from the glans penis." Dr. Beck said this fragment was the carefully transplanted remnant of the prepuce. While Dr. Beck fully realized that failures are possible in the hands of even the best experts, in this patient the fault was not the method but the extreme nervous condition of the patient.

BOOK REVIEWS.

Biographic Clinics. Vol. II. By George M. Gould, M.D. P. Blakiston's Son & Co., Philadelphia.

There are few literary diversions more interesting and innocent than trailing an idea through one's favorite authors with a pencil. One can underline all passages bearing on one's subject, ignoring those that upset one's theories, jot the page number of the selections on a blank page, and transfer them at leisure to a large notebook. After several years of this pleasurable pastime one will have material enough to make an original book of one's own, which, if one should be fortunate enough to excite the animosity of critics, one might sell with some profit, and much éclat.

We have ourselves read somewhat with the idea of collecting material to show that heroines with red hair are possessed of indomitable wills and great energy of character inherited from a remote but famous ancestor; but we doubt whether we could bring out anything so convincing as the "Strange Mystery of the Disease of Fourteen," which Dr. George M. Gould has evolved from his extensive biographical reading. In his second volume of Biographic Clinics, the Fourteen are sons and daughters of genius, that lived in the last century, and have illumed literature, but who, it seems, all unknowingly lived martyr's lives due to eye strain. The continued excerpts from George Eliot's familiar letters, "very irritated to-day," "terrible headache," are repeated in the quotations of the letters of Carlyle and his wife, Darwin, Nietzsche, Wagner, Spencer and the rest, all of whom foolishly attributed their suffering to tire of city life, care, work, indigestion, and who took the advice of the very famous, but misinformed physicians who attended them, to go to Italy, or the country, or the Highlands.

We remember, from the casual reading of our own unnoted copies of their biographies, that this change frequently benefited them, that De Quincey and Browning were in good form when they walked and walked; but we see now that it was a "pitiful waste of time" for, as Dr. Gould points out, "fully three-fourths of Carlyle's working time and ability were spent in horse-back riding, walking, and in recovering from the exhaustion of writing," while "much of Mrs. Carlyle's life was spent in thirty to sixty hour continuous vomiting," although another excerpt says that for ten years she walked six to ten miles a day, and Darwin spent hours "walking like a dumb animal about his sand-walk, or more foolishly enduring the brutal water-cure." What would not their literary output have been had their physician fitted them with spectacles, so that they could have done a full day's work.

But Dr. Gould calls our attention to the fact that most of the fourteen affected to scorn spectacles, and had they been willing to wear them they could not have obtained scientifically correct ones. And this is the strong point. The neurologists and ophthalmologists do not know their business. They will persist in attributing to hereditary, and brain work, and lack of fresh air, millions of cases of migraine and neurasthenia that ought to be called "eye strain," and when they do suggest spectacles they only aggravate the trouble by prescribing wrong ones.

Dr. Gould expected that when he pointed out in his first volume the enormity of the mistake of the medical profession in ignoring this truth, that the ophthalmologists, at least would be grateful to him; but the levity of some and the bitterness of others has naturally hurt his feelings, although he takes pains to state that he is "neither discouraged nor scornful."

Even when a "great and famous ophthalmic surgeon," to quote his own words, "told him that he had examined large numbers of patients who complained of the same troubles as Darwin, Wagner, Parkman and the rest, and found that they had no optical defects whatever," yet Dr. Gould was patient with him, and only told him, to quote again, "that all history is full of instances of the failure of the official leaders or representatives of religious art and science to recognize the new truth which finally supplanted the pitiable truth they stood for."

With a view to convincing his fellow practitioners that millions of patients are suffering from eye strain, and that they are merely encouraging quacks, by seeking other causes of difficulty Dr. Gould cites "sixty-eight reasons why 'glasses did not give relief.'" Among others relating to a knowledge of refraction in which it appears that oculists and opticians are equally wanting, he states that (6) the oculist may not be morally right-minded in carrying on his work; (7) he may not be intellectually fitted or capable of doing this particular kind of work; (8) he may not be sufficiently painstaking in attention to mathematic accuracy and the slightest details.

We call the attention of the distinguished oculists of the country to these and the remaining 65 reasons, for it may be that they are ignorantly caring for some genius, and it might in the end be written of their patients, as Dr. Gould has done of the famous pair: "Eye strain made George Eliot and Henry Lewes great sufferers, compelled them to waste much of their lives in walking, and killed them at the early age of 61 years."

Disinfection and the Preservation of Food. By Samuel Rideal, D.Sc., Lecturer on Chemistry in St. George's Hospital Medical School. John Wiley & Sons, New York.

This is an extensive volume of nearly 500 pages, devoted exclusively to the methods of disinfection and preservation of food.

It is of interest in the first place to the large number of manufacturers who put up preserved foods, and it is moreover of vital importance to those who have to deal with the testing of preserved foods.

To army physicians, to the medical man in localities where fresh food is difficult to obtain, such a work is indispensable.

We can recommend it most heartily to sanitarians and practitioners alike. It is largely devoted to technical features and methods, but it will undoubtedly be found useful in the camp, hotel, and field, as well as in the porkpacker's establishment.

A Manual of the Practice of Medicine. By A. A. Stevens, A.M., M.D. Sixth edition. Thoroughly revised. W. B. Saunders & Co., Philadelphia, New York and London.

Dr. Stevens' Manual of the Practice of Medicine is so well and favorably known that it needs no commendation of ours. It is really a very marvelous condensation of the absolutely necessary in medicine. It is no wonder that it is in its sixth edition in ten years. In this edition the entire section on diseases of the digestive system has been rewritten as well as individual articles in other parts of the book. Like most of the manuals for students Dr. Stevens' little book of 550 pages may well prove a faithful companion throughout life to the practitioner, who, especially in its flexible cover, can readily carry it with him and find valuable hints and practical suggestions even at the bedside itself. There is many a large text-book of medicine that is not as satisfactory a guide to the practitioner.
